TDAM: a Topic-Dependent Attention Model for Sentiment Analysis

Gabriele Pergola*, Lin Gui, Yulan He*

University of Warwick, Coventry, UK

Abstract

We propose a topic-dependent attention model for sentiment classification and topic extraction. Our model assumes that a global topic embedding is shared across documents and employs an attention mechanism to derive local topic embedding for words and sentences. These are subsequently incorporated in a modified Gated Recurrent Unit (GRU) for sentiment classification and extraction of topics bearing different sentiment polarities. Those topics emerge from the words’ local topic embeddings learned by the internal attention of the GRU cells in the context of a multi-task learning framework. In this paper, we present the hierarchical architecture, the new GRU unit and the experiments conducted on users’ reviews which demonstrate classification performance on a par with the state-of-the-art methodologies for sentiment classification and topic coherence outperforming the current approaches for supervised topic extraction. In addition, our model is able to extract coherent aspect-sentiment clusters despite using no aspect-level annotations for training.

Keywords: sentiment analysis, neural attention, topic modeling

1. Introduction

In recent years, attention mechanisms in neural networks have been widely used in various tasks in Natural Language Processing (NLP), including machine

Translation (Bahdanau et al., 2015; Luong et al., 2015; Vaswani et al., 2017), image captioning (Xu et al., 2015), text classification (Yang et al., 2016; Chen et al., 2016; Ma et al., 2017) and reading comprehension (Hermann et al., 2015; Wang et al., 2017). Attention mechanisms are commonly used in models for processing sequence data that instead of encoding the full input sequence into a fixed-length vector learn to “attend” to different parts of the input sequence, based on the task at hand. This is equivalent to giving the model the access to its internal memory which consists of the hidden states of the sequence encoder. Typically soft attention is used which allows the model to retrieve a weighted combination of all memory locations.

One advantage of using attention mechanisms is that the learned attention weights can be visualized to enable intuitive understanding of what contributes the most to the model’s decision. For example, in sentiment classification, the visualization of word-level attention weights can often give us a clue as to why a given sentence is classified as positive or negative. Words with higher attention weights can be sometimes indicative of the overall sentence-level polarity (for example, see Figure 1). This inspires us the development of a model for the extraction of polarity-bearing topics based on the attention weights learned by a model.

However, simply using the attention weights learned by the traditional attention networks such as the Hierarchical Attention Network (HAN) (Yang et al., 2016)
would not give good results for the extraction of polarity-bearing topics, since in these models the attention weight of each word is calculated as the similarity between the word’s hidden state representation with a context vector shared across all the documents. There is no mechanism to separate words into multiple clusters representing polarity-bearing topics.

Therefore, in this paper, we propose a novel Topic-Dependent Attention Model (TDAM) in which a global topic embedding (i.e., a matrix with \( K \) topic vectors) is shared across all the documents in a corpus and captures the global semantics in multiple topical dimensions. When processing each word in an input sequence, we can calculate the similarity of the hidden state of the word with each topic vector to get the attention weight along a certain topical dimension. By doing so, we can subsequently derive the local topical embedding for the word by the weighted combination of the global topic embeddings, indicating the varying strength of the association of the word with different topical dimensions. We use Bidirectional Gated Recurrent Unit (BiGRU) to model the input word sequence; we modify the GRU cells to derive a hidden state for the current word which simultaneously takes into account the current input word, the previous hidden state and local topic embedding.

Our proposed formulation of topical attention is somewhat related to the consciousness prior proposed in Bengio (2017) in which the conscious state value corresponds to the content of a thought and can be derived by a form of attention selecting a “small subset of all the information available” from the hidden states of the model. Analogously, we first assume the corpus is characterized by a global topic embedding. Then, we learn how to infer the local topic mixture for each analyzed word/sentence combining hidden states and global topic embedding with attention.

In this paper, we describe TDAM and present its application to sentiment classification in reviews by a hierarchical and multi-task learning architecture. The aim is to evaluate a review’s polarity by predicting both the rating and the

\[ \text{https://github.com/gabrer/topic_dependent_attention_model} \]
domain category of the review (e.g. restaurant, service, health, etc.). Often these reviews contain statements that can be fully specified only by the contextual topic. To illustrate, in Figure 2 we show two review extracts, one for a restaurant and another for a dishwasher. Interestingly, the same expression “not to clean the plates” can be regarded as positive for food while it bears a negative polarity for kitchen equipment. Thus, it is important to jointly consider both topic and sentiment shared over words for better sentiment analysis.

In particular, we make the following contributions:

• We design a neural architecture and a novel neural unit to analyze users’ reviews while jointly taking into account topics and sentiments. The hierarchical architecture makes use of a global topic embedding which encodes the shared topics among words and sentences; while the neural unit employs a new internal attention mechanism which leverages the global topic embeddings to derive a local topic representation for words and sentences.

• We assess the benefit of multi-task learning to induce representations which are based on documents’ polarities and domains. Our experiments show that combining the proposed architecture with the modified GRU unit is an effective approach to exploit the polarity and domain supervision for accurate sentiment classification and topic extraction.

• As a side task to evaluate the sentence representations encoded by TDAM, we extract aspect-sentiment clusters using no aspect-level annotations during the training; then, we evaluate the coherence of those clusters. Experiments demonstrate that TDAM achieves state-of-the-art performance in extracting clusters whose sentences share coherent polarities and belong
to common domains.

To evaluate the performance of our model, we conduct experiments on both Yelp and Amazon review datasets (see §4.1). We compare the sentiment classification performance with state-of-the-art models (§5). Then, visualization of topical attention weights highlights the advantages of the proposed framework (§5.2). We also evaluate how meaningful are the inferred representations in term of topic coherence (§5.3) and based on their capability to cluster sentences conveying a shared sentiment about a common aspect (§5.4).

2. Related Work

Our work is related to three lines of research.

Hierarchical structure for text classification. Many works have recently proposed to incorporate prior knowledge about the document structure directly into the model architecture to enhance the model’s discriminative power in sentiment analysis. A hierarchical model incorporating user and product information was first proposed by Tang et al. (2015) for rating prediction of reviews. Similarly, Chen et al. (2016) combined user and product information in a hierarchical model using attention (Bahdanau et al., 2015); here, attention is employed to generate hidden representations for both products and users. Yang et al. (2016) used a simple and effective two-level hierarchical architecture to generate document representations for text classification; words are combined in sentences and in turn, sentences into documents by two levels of attention. Liu & Lapata (2018) further empowered the structural bias of neural architectures by embedding a differentiable parsing algorithm. This induces dependency tree structures used as additional discourse information; an attention mechanism incorporates these structural biases into the final document representation. Yang et al. (2019) introduced Coattention-LSTM for aspect-based sentiment analysis which designs a co-attention encoder alternating and combining the context and target attention vectors of reviews.
Combining topics with sequence modeling. There has been research incorporating topical information into the sequence modeling of text or use variational neural inference for supervised topic learning. Dieng et al. (2017) developed a language model combining the generative story of Latent Dirichlet Allocation (LDA) (Blei et al., 2003) with the word representations generated by a recurrent neural network (RNN). Stab et al. (2018) proposed incorporating topic information into some gates in Contextual-LSTM, improving generalization accuracy on argument mining. Abdi et al. (2019) proposed to directly incorporate word and sentence level features about contextual polarity, type of sentence and sentiment shifts by encoding prior knowledge about part-of-speech (POS) tagging and sentiment lexicons. Kastrati et al. (2019) enhanced document representations with knowledge from an external ontology and encoded documents by topic modeling approaches. Jin et al. (2018) proposed to perform topic matrix factorization by integrating both LSTM and LDA, where LSTM can improve the quality of the matrix factorization by taking into account the local context of words. Card et al. (2018) proposed a general neural topic modeling framework which allows incorporating metadata information with a flexible variational inference algorithm. The metadata information can be labels driving the topic inference and used for the classification task, analogous to what proposed in a Bayesian framework by Mcauliffe & Blei (2008) with supervised Latent Dirichlet Allocation (S-LDA).

Multi-task learning. Several variants of multi-task learning with neural networks have been recently used for sentiment analysis. Wu & Huang (2016) proposed a multi-task learning framework for microblog sentiment classification which combines common sentiment knowledge with user-specific preferences. Liu et al. (2016) employed an external memory to allow different tasks to share information. Liu et al. (2017) proposed an adversarial approach to induce orthogonal features for each task. Chen & Cardie (2018) applied a different training scheme to the adversarial approach to minimize the distance between feature distributions across different domains. Zhang et al. (2018) proposed to use an embedded representation of labels to ease the gener-
ation of cross-domain features. [Zheng et al., 2018] proposed to share the same sentence representation for each task which in turn can select the task-specific information from the shared representation using an ad-hoc attention mechanism. [Wang et al., 2018] applied multi-task learning for microblog sentiment classification by characterizing users across multiple languages.

3. Topic-Dependent Attention Model

We illustrate the architecture of our proposed Topic-Dependent Attention Model (TDAM) in Figure 3 which is a hierarchical and multi-level attention framework trained with multi-task learning.

Concretely, at the word sequence level (the bottom part of Figure 3), we add a word-level topic attention layer which computes the local topic embedding of

![](https://example.com/figure3.png)

Figure 3: Topic-Dependent Attention Model (TDAM).
each word based on the global topic embedding and the current hidden state. Such word-level local topic embedding indicates how strongly each word is associated with every topic dimension, which is fed into the Bi-GRU cell in the next time step for the derivation of the hidden state representation of the next word. Bi-GRU is used to capture the topical contextual information in both the forward and backward directions. We then have a word attention layer which decides how to combine the hidden state representations of all the constituent words in order to generate the sentence representation. At the sentence-level, a similar two-level attention mechanism is used to derive the document representation, which is fed into two separate softmax layers for predicting the sentiment class and the domain category. Each of the key components of TDAM is detailed below.

3.1. Topic-Dependent Word Encoder

Given a word sequence $x_i = (x_{i1}, \ldots, x_{iT})$, where $x_{it} \in \mathbb{R}^d$ is a word embedding vector with $d$ dimensions, we use Bi-GRU to encode the word sequence. The hidden state at each word position, $h_{it}$, is represented by the concatenation of both forward and backward hidden states, $h_{it} = [\overrightarrow{h_{it}}, \overleftarrow{h_{it}}]$, which captures the contextual information of the whole sentence centred at $x_{it}$.

We assume there are $K$ global topic embeddings shared across all documents, where each topic has a dense and distributed representation, $e_k \in \mathbb{R}^n$, with $k = \{1, \ldots, K\}$, which is initialized randomly and will be updated during model learning.

At each word position, we can calculate the word-level topic weight by measuring the distance between the word vector and each global topic vector. We first project $h_{it}$ using a one-layer MLP and then compute the dot products between the projected $h_{it}$ and global topic vectors $e_k$, $k = \{1, \ldots, K\}$ to generate
the weight of local topic embedding for the corresponding word position.

\[
\begin{align*}
  u_{it} &= \tanh(W_w h_{it}) \quad (1) \\
  \alpha^k_{it} &= \text{softmax}(u_{it}^\top e_k) \quad (2)
\end{align*}
\]

where \(W_w \in \mathbb{R}^{n \times n}\) and \(k \in \{1, \ldots, K\}\). The local topic embedding is then:

\[
q_{it} = \sum_{k=1}^{K} \alpha^k_{it} \otimes e_k \quad (3)
\]

with \(q_{it} \in \mathbb{R}^n\), \(\alpha_{it} \in \mathbb{R}^K\). Here, \(\otimes\) denotes multiplication of a vector by a scalar.

We add the local topic embedding into the GRU cell to rewrite the formulae as follows:

\[
\begin{align*}
  r_t &= \sigma(W_r x_t + U_r h_{t-1} + V_r q_{t-1}) \quad (4) \\
  z_t &= \sigma(W_z x_t + U_z h_{t-1} + V_z q_{t-1}) \quad (5) \\
  \hat{h}_t &= \tanh(W_h x_t + r_t \odot (U_h h_{t-1} + V_h q_{t-1})) \quad (6) \\
  h_t &= (1 - z_t) \odot h_{t-1} + z_t \odot \hat{h}_t \quad (7)
\end{align*}
\]

where \(\sigma(\cdot)\) is the sigmoid function, all the \(W, U\) and \(V\)s are weight matrices which are learned in the training process, \(\odot\) denotes the element-wise product.

The reset gate \(r_t\) controls how much past state information is to be ignored in the current state update. The update gate \(z_t\) controls how much information from the previous hidden state will be kept. The hidden state \(h_t\) is computed as the interpolation between the previous state \(h_{t-1}\) and the current candidate state \(\hat{h}_t\).

In the above formulation, the hidden state in the current word position not only depends on the current input and the previous hidden state, but also takes into account the local topic embedding of the previous word. Since some of those words may be more informative than others in constituting the overall sentence.
meaning, we aggregate these representations with a final attention mechanism:

\[ v_{it} = \tanh(W_v h_{it}) \]  
(8)

\[ \beta_{it} = \text{softmax}(v_{it}^T v_w) \]  
(9)

\[ s_i = \sum_{t=1}^{t} \beta_{it} \otimes h_{it} \]  
(10)

where \( \beta_{it} \) is the attention weight for the hidden state \( h_{it} \) and \( s_i \in \mathbb{R}^n \) is the sentence representation for the \( i \)th sentence.

3.2. Sentence Encoder

Given each sentence representation \( s_i \) in document \( d \) where \( i = \{1, ..., d_L\} \) and \( d_L \) denotes the document length, we can form the document representation using the proposed topical GRU in a similar way. For each sentence \( i \), its context vector is \( h_i = [\overrightarrow{h_i}, \overleftarrow{h_i}] \), which captures the contextual information of the whole document centred at \( s_i \).

We follow an approach analogous to the topic-dependent word encoder and generate the local topic embedding for \( i \)th sentence:

\[ u_i = \tanh(W_s h_i) \quad W_s \in \mathbb{R}^{n \times n} \]  
(11)

\[ \alpha_i^k = \text{softmax}(u_i^T e_k) \quad k \in \{1, ..., K\} \]  
(12)

\[ q_i = \sum_{k=1}^{K} \alpha_i^k \otimes e_k \quad q_i \in \mathbb{R}^n \]  
(13)

where \( q_i \) is local topic embedding for sentence \( i \). We add the local topic embedding into the GRU cell as in Eq. \( \ref{eq:4} \) - \( \ref{eq:7} \).

Analogously to the word encoder, those sentences contribute differently to the overall document meaning; thus, we aggregate these representations with an attention mechanism similar to the final attention mechanism described in Section 3.1.
3.3. Multi-Task Learning

Finally, for each document \(d\), we feed its representation \(m_d\) into the task-specific softmax layers, each one defined as follows:

\[
p_d = \text{softmax}(W_d m_d) \quad W_d \in \mathbb{R}^{C \times n}
\]

where \(C\) denotes the total number of classes. The training loss is defined as the total cross-entropy of all documents computed for each task:

\[
L_{\text{task}} = -\sum_{d=1}^{D} \sum_{c=1}^{C} y_{d,c} \log p_{d,c}
\]

where \(y_{d,c}\) is the binary indicator (0 or 1) if class label \(c\) is the correct classification for document \(d\). We compute the overall loss as a weighted sum over the task-specific losses:

\[
L_{\text{total}} = \sum_{j=1}^{J} \omega_j L(\hat{y}^{(j)}, y^{(j)})
\]

where \(J\) is the number of tasks, \(\omega_j\) is the weight for each task, \(y^{(j)}\) are the ground-truth labels in task \(j\) and \(\hat{y}^{(j)}\) are the predicted labels in task \(j\).

3.4. Topic Extraction

Once our model is trained, we can feed the test set and collect the local topic embedding \(q_{it}\) associated to each word (Eq. 3), collecting a set of \(n\)-dimensional vectors for each occurrence of words in text. This mechanism can be interpreted analogously to models generating deep contextualised word representations based on language model, where each word occurrence has a unique representation based on the context in which it appears [Peters et al., 2018; Devlin et al., 2019].

The local representation \(q_{it}\) in our model results from the interaction with the global topic embeddings, which encode the word co-occurrence patterns characterizing the corpus. We posit that these vectors can give us an insight about the topic and polarity relations among words. Therefore, we first project these representations into a two-dimensional space by applying the t-SNE [Van der
Maaten & Hinton [2008]; then, the resulting word vectors are clustered by applying the K-means algorithm. We create a fixed number of clusters $k$, whose value is tuned by maximizing the topic coherence for $k \in [50, 100, 200]$. We use the distance of each word to the centroid of a topic cluster to rank words within a cluster. Similarly, we cluster sentences based on the representation resulting from the sentence-level topical attention layer. This encoding synthesises both the main topic and polarity characterizing the sentence.

4.1. Datasets

We gathered two balanced datasets of reviews from the publicly available Yelp Dataset Challenge dataset in 2018 and the Amazon Review Dataset\(^3\) (McAuley et al. 2015), preserving the meta-information needed for a multi-task learning scenario. Each review is accompanied with one of the three ratings, positive, negative or neutral and comes from five of the most frequent domains\(^4\).

\(^3\)http://jmcauley.ucsd.edu/data/amazon/
\(^4\)For Yelp: restaurants, shopping, home services, health & medical and automotive. For Amazon: Pet supplies, electronics, health personal care, clothes shoes and home and kitchen.
Those ratings are the human labeled review scores regarded as gold standard sentiment labels during the experimentation. For each pair of domain and rating, we randomly sample 3,000 reviews, collecting a total of 75,000 reviews. To make it possible for others to replicate our results, we make both the dataset and our source code publicly available[4]. Table 1 summarizes the statistics of the datasets.

4.2. Baselines

We train our proposed TDAM with multi-task learning to perform sentiment and domain classification simultaneously. We compare the performance of TDAM with the following baselines on both sentiment classification and topic extraction:

- **BiLSTM** [Hochreiter & Schmidhuber, 1997] or **BiGRU** [Cho et al., 2014]: Both models consider a whole document as a single text sequence. The average of the hidden states is used as features for classification.

- **Hierarchical Attention Network (HAN)** [Yang et al., 2016]: The hierarchical structure of this attention model learns word and sentence representations through two additive attention levels.

- **Supervised-LDA (S-LDA)** [McAuliffe & Blei, 2008]: It builds on top of the latent Dirichlet allocation (LDA) [Blei et al., 2003] adding a response variable associated with each document (e.g. review’s rating or category).

- **Scholar** [Card et al., 2018]: A neural framework for topic models with metadata incorporation without the need of deriving model-specific inference. When metadata are labels, the model infers topics that are relevant to those labels.

The baselines, such as BiLSTM, BiGRU and HAN, are additionally trained with multi-task learning, similar to the setup of our model.

4.3. Parameter Settings

For our experiments, we split the dataset into training, development and test set in the proportion of 80/10/10 and average all the results over 5-fold cross-validation. We perform tokenization and sentence splitting with SpaCy\footnote{https://spacy.io/}. We do not filter any words from the dataset during the training phase; although we use the default preprocessing for models like S-LDA and SCHOLAR. Word embeddings are initialized with 200-dimensional GloVe vectors\footnote{https://github.com/DmitryUlyanov/Multicore-TSNE} (Pennington et al., 2014). We tune the models’ hyperparameters on the development set via a grid search over combinations of learning rate $\lambda \in [0.01, 0.1]$, dropout $\delta \in [0, 0.6]$ and topic vector’s size $\gamma_t \in [50, 200]$. Matrices are randomly initialized to be semi-orthogonal matrix\footnote{http://scikit-learn.org/stable/modules/clustering.html} (Saxe et al., 2014); all the remaining parameters are randomly sampled from a uniform distribution in $[-0.1, 0.1]$. We adopt Adam optimizer\footnote{https://github.com/DmitryUlyanov/Multicore-TSNE} (Kingma & Ba, 2015) and use batch size of 64, sorting documents by length (i.e. number of sentences) to accelerate training convergence; we also apply batch normalization as additional regulariser (Cooijmans et al., 2017).

Once the model is trained, we extract the local topic embedding for each word occurrence in text as its contextualized word representation. These vectors are then projected to a lower-dimensional space by means of a multi-core implementation of a Tree-Based algorithm for accelerating t-SNE\footnote{https://spacy.io/} (Van Der Maaten, 2014). Then, we cluster these words with K-means\footnote{https://scikit-learn.org/stable/modules/clustering.html}.

5. Evaluation and results

We report and discuss the experimental results obtained on three evaluation tasks, sentiment classification topic extraction and sentence cluster extraction.

5.1. Sentiment Classification

We train the models under two different settings: a single and a multi-task learning scenario, where we optimize over the only review polarity or over the
It can be observed from the table that BiLSTM and BiGRU perform similarly. With hierarchical attention mechanism at both the word level and the sentence level, HAN boosts the performance by nearly 10% on Yelp and 6% on Amazon compared to BiLSTM and BiGRU. For the neural topic modeling approaches, Scholar outperforms traditional S-LDA by a large margin. However, Scholar is still inferior to HAN. With our proposed topical attentions incorporated into the hierarchical network structure, TDAM further improves on HAN. Multi-task learning does not seem to bring any benefit to sentiment classification for baseline models, though it further improves the performance of TDAM slightly.

### 5.2. Effectiveness of Topical Attention

If we remove the topical attention and substitute our modified GRU with standard GRU, then the resulting architecture is similar to HAN ([Yang et al., 2016](#)) for a multi-task learning setting. In this section, we visualize the attention

weights learned by HAN and TDAM to compare their results. Examples are shown in Figure 1. In TDAM, topical words such as dentist or the dentist’s name, Rebecca, are regarded as relevant by the model. Along with them, it focuses on words bearing a strong sentiment, such as nicest or happy. These weights are compared with the attention weights learned by the HAN, showing that it primarily focuses sentiment words and overlooks other topical words, such as dentist.

5.3. Topic Coherence Evaluation

Among the baselines, S-LDA and SCHOLAR are topic modeling methods and therefore can directly output topics from text. In addition, we can follow the topic extraction procedure described in Section 3.4 to extract topics from HAN to gain an insight into the learned representations. We thus compare the topic extraction results of TDAM with these three models. Also, as previously shown in (Card et al., 2018), higher regularisation on SCHOLAR produced better topics. Therefore, we also report the results using SCHOLAR with higher regularization, named as SCHOLAR-R.

To evaluate the quality of topics, we use the topic coherence measure proposed in (Röder et al., 2015), which has been shown outperforming all the other

9https://github.com/dice-group/Palmetto
existing topic coherence measures. We can observe from Table 3 that HAN gives the worse topic coherence results, showing that simply extracting topics using the attention weights is not feasible. With the incorporation of domain category information through multi-task learning, HAN-Mtl gives slightly better coherence results. Among topic modeling approaches, SCHOLAR-R with higher regularization generates more coherence topics compared to SCHOLAR, which outperforms S-LDA. TDAM gives similar topic coherence results as SCHOLAR-R on some topic numbers. TDAM-Mtl improves over TDAM and generates the best coherence results on 2 out of 3 topic settings for both Yelp18 and Amazon, showing higher coherence scores overall.

5.4. Aspect-Polarity Coherence Evaluation

To assess the effectiveness of our proposed TDAM in extracting polarity-bearing topics, we use the annotated dataset provided in the SemEval 2016 Task 5 for aspect-based sentiment analysis\footnote{http://alt.qcri.org/semeval2016/task5/} this provides sentence-level annotations about different aspects (e.g. FOOD#QUALITY) and polarities (pos, neut, neg) in restaurant and laptop reviews.

We join the training set of restaurant and laptop reviews with the Yelp18 and Amazon dataset, respectively. With the same approach adopted for topic extraction, we use the test sets to generate sentence clusters and evaluate their aspect-polarity coherence, defined as the ratio of sentences sharing a common aspect and sentiment in a cluster. For the two topic modeling approaches, S-LDA and SCHOLAR, we generate sentence clusters based on the generative probabilities of sentences conditional on topics. Note that although the SemEval dataset provides the sentence-level annotations of aspects and polarities, these were NOT used for the training of the models here. We only use the gold standard annotations of aspects and polarities in the test set to evaluate the quality of the extracted polarity-bearing topics.

We generate multiple clusters, i.e. (50,100,150), representing polarity-bearing
aspects and report the results in Table 4, which shows the ratio of sentence clusters with more than threshold sentences sharing a common aspect (values in brackets) or a common aspect-polarity. We can observe that the topic modeling approaches struggle in generating coherent aspect-polarity clusters with at least 50% of common aspect-polarities. The two hierarchical models, HAN and TDAM, have significantly more coherent aspect-polarity clusters compared to S-LDA and SCHOLAR, and both benefit from multi-task learning. For all the models, results on SemEval-Restaurant are better than those obtained on SemEval-Laptop. This might be partly attributed to the abundant restaurant reviews on Yelp18 compared to the laptop-related reviews on Amazon. Overall, TDAM-Mtl gives the best results.

We also show some example sentence clusters produced by HAN and TDAM under multi-task learning in Table 5. HAN discriminates rather effectively positive sentences (the majority in the cluster) from negative and neutral ones. However, despite several sentences sharing the same polarity, their topics/aspects are quite heterogeneous. TADM phrases are rather coherent overall, both in terms of topics and expressed sentiment.

These results are encouraging. Our TDAM is able to detect coherent aspects and also polarity-bearing aspects despite using no aspect-level annotations at all. Considering it is very time consuming to provide aspect-level annotations, TDAM could be used to bootstrap the training of aspect-based sentiment detectors.

6. Conclusion

We have presented a new topic-dependent attention model for sentiment classification and topic extraction. The conjunction of topical recurrent unit and multi-task learning framework has been shown to be an effective combination to generate representations for more accurate sentiment classification, meaningful topics and for side task of polarity-bearing aspects detection. In future, we will extend the model to deal with discourse-level sentiments (Feng & Hirst 2012).
Table 4: Ratio of clusters where at least $x$% sentences sharing the same aspect (values in brackets) and sharing the same aspect-polarity (i.e. both aspect and polarity are correct).
