Abstract.

The superconducting properties of rhombohedral $LaIr_3$ were examined using susceptibility, resistivity, heat capacity, and zero-field (ZF) and transverse-field (TF) muon spin relaxation and rotation (μSR) measurements. The susceptibility and resistivity measurements confirm a superconducting transition below $T_C = 2.5(1)$ K. Two successive transitions are observed in the heat capacity data, one at $T_C = 2.5$ K and a second at 1.2 K below T_C. The heat capacity jump is $\Delta C/\gamma T_C \sim 1.0$ which is lower than 1.43 expected for Bardeen-Cooper-Schrieffer (BCS) weak-coupling limit. Transverse-field-μSR measurements reveal a fully gapped $s-$wave superconductivity with $2\Delta(0)/k_BT_C = 3.31(8)$, which is small compared to BCS value of 3.56, suggesting weak-coupling superconductivity. The magnetic penetration depth, $\lambda_L(0)$, estimated from TF-μSR gives $\lambda_L(0) = 386(3)$ nm, a superconducting carrier density $n_s = 2.9(1)\times 10^{27}$ carriers m^{-3} and a carrier effective-mass enhancement factor $m^* = 1.53(1)m_e$. ZF-μSR data show no evidence for any spontaneous magnetic fields below T_C, which demonstrates that time-reversal symmetry is preserved in the superconducting state of $LaIr_3$.

1. Introduction

The search for unconventional superconductivity in $5d$ transition metal-based compounds is one of the most fascinating and significant problems in condensed matter physics [1, 2, 3, 4]. Due to the presence of strong spin-orbit (SO) coupling effects, the $5d$ transition metal compounds have been extensively studied to investigate the correlation between strong SO coupling and unconventional superconductivity [5, 6]. Similar energy scales for the comparatively weak electronic correlations (0.5 to 3 eV), crystal-field effects (1 to 5 eV) and strong relativistic SO coupling effects (0.1 to 1 eV) provide an opportunity to investigate the science emerging from competing orbital, spin, charge, and lattice degrees of freedom [7, 8]. For example, pressure-induced superconductivity in 1T-TaS_2 [9], in noncentrosymmetric $CePt_3Si$ [10], and in the geometrically frustrated pyrochlore oxides $Cd_2Re_2O_7$ [11] and KOs_2O_6 [12]. In iridium-containing compounds, superconductivity has been reported in materials such as $IrSe_2$, $Cu_{1-x}Zn_xIr_2S_4$, $CeIrSi_3$, ScIrP, LaIrP and LaIrAs, and in the ternary $ThCr_2Si_2$-type compounds $BaIr_2P_2$ and $SrIr_2As_2$ [13, 14, 15, 16, 17, 18]. In the case of the rare-earth Ir based superconductors, their electronic characteristics are anticipated to arise principally from the rare-earths, rather than the Ir. Nevertheless, there are a few materials such as $CaIr_2$ [19], IrGe [20], and $Mg_{10}Ir_{19}B_{16}$ [21], where the superconductivity emerges from the Ir $5d$ states. Now, with the discovery of $LaIr_3$, there is a simple La-Ir superconductor with strong spin-orbit-coupling whose characteristics are controlled by the Ir $5d$ bands at the Fermi surface.

Recently, Haldolaarachchige *et al.* [22] reported that $LaIr_3$ shows superconductivity with a T_C between 2.45 and 3.3 K and $\mu H_{c2}(0) = 38.4$ kOe, where the Fermi surface is governed by the Ir $5d$ bands that are heavily influenced by spin-orbit coupling and there is no strong contribution from the La-orbitals near E_F. $LaIr_3$ is, therefore, one of the few superconductors where $5d$ bands play a principal role in the appearance of superconductivity. Furthermore, a three-dimensional metallic character is seen from the band structure calculations; many bands with large dispersion cross E_F [22]. $LaIr_3$ forms with a rhombohedral crystal structure with the space group $R\bar{3}m$ (166, D^5_{3d}). There are two crystallographically inequivalent La sites and three Ir sites [22]. To examine the role the lanthanide elements and the spin-orbit coupling effects arising from the Ir $5d$ bands play in determining the superconducting properties, the study of other rhombohedral RIr_3 materials (R is a lanthanide with $4f$ electrons) [23, 24] will be important. In particular, compounds with partly filled $4f$ orbitals, such as Ce and Pr, may exhibit magnetism and possibly superconductivity. Sato *et al.* [24] reported that $CeIr_3$ is a type-II superconductor with a $T_C = 3.4$ K, which is the second highest T_C amongst the Ce-based compounds. The small value of the Sommerfield coefficient, 23 mJ K^{-2} $mole^{-1}$, indicates that $CeIr_3$ is a weakly correlated electron system [24]. The band structure and Fermi surface of $LaIr_3$ with and without spin-orbit coupling differ significantly [22], which indicates that spin-orbit coupling is expected to have a strong effect on the superconducting properties of $LaIr_3$. The role of spin-orbit coupling is further confirmed by the evidence that T_C is lower in the isostructural $LaRh_3$ compound [25], where the spin-orbit coupling is negligible. $LaIr_3$ is thus a rare example of a lanthanide superconductor with strong spin-orbit coupling arising from the Ir-$5d$ electrons.

In this paper, we examine the superconducting features of $LaIr_3$ using susceptibility, resistivity, heat capacity, and zero-field (ZF) and transverse-field (TF) muon spin relaxation and rotation (μSR) measurements. The TF-μSR measurements suggest an isotropic $s-$wave

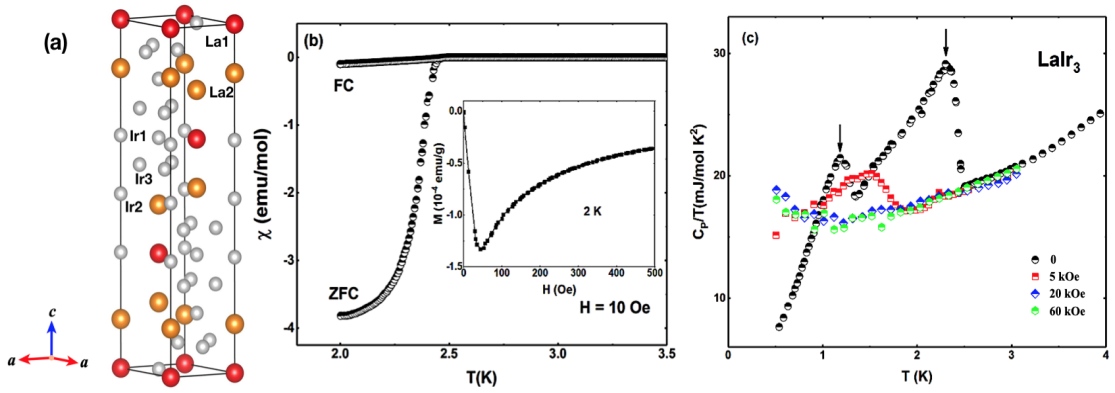

Figure 1. (a) Crystal structure of rhombohedral $LaIr_3$. model can describe the superconducting ground state of $LaIr_3$. The ZF-μSR data show no evidence for internal magnetic fields below T_C, implying time-reversal symmetry is preserved for $LaIr_3$.

2. Experimental Details

Polycrystalline samples of $LaIr_3$ were prepared by arc melting the constituent elements using a tri-arc furnace. The crystal structure was determined by powder X-ray diffraction utilizing a Panalytical X-Pert Pro diffractometer. Energy dispersive X-ray spectroscopy (EDS) in an FEI XL30 FEG-SEM system was used to investigate the stoichiometry (ratio of La:Ir) of the sample, and revealed an average chemical composition of $LaIr_{3.1}$, a composition with a slight excess of Ir. Zero-field-cooled (ZFC) and field-cooled (FC) DC magnetic susceptibility measurements were made using a Quantum Design (QD) Magnetic Property Measurement System, superconducting quantum interference device magnetometer. Heat capacity was measured as a function of temperature T down to 350 mK in applied magnetic fields H of up to 60 kOe using a two-τ relaxation technique in a QD Physical Property Measurement System (PPMS) with a He-3 insert. The measurements were carried out on a solid piece of a sample taken from the arc-melted button. Resistivity measurements as a function of temperature at fixed applied field and as a function of applied field at fixed temperature were made in a QD PPMS. The sample was cut into an approximately rectangular bar. Silver wires were fixed to the sample in a four-point geometry using DuPont 4929N silver paste. Measurements at higher temperature (1.8 to 3 K) in fields up to 6 kOe were made using an AC technique with an excitation current of 1 mA at a frequency of 113 Hz. Measurements at lower temperature (0.5 to 2 K) in fields up to 12 kOe were made with a He-3 insert using a pseudo-AC method, with a 400 mA DC current passed through the sample in both directions. The upper critical field was taken to be at the midpoint of the transition from the normal into the superconducting state.

μSR measurements were performed using the MuSR spectrometer at the ISIS Neutron and

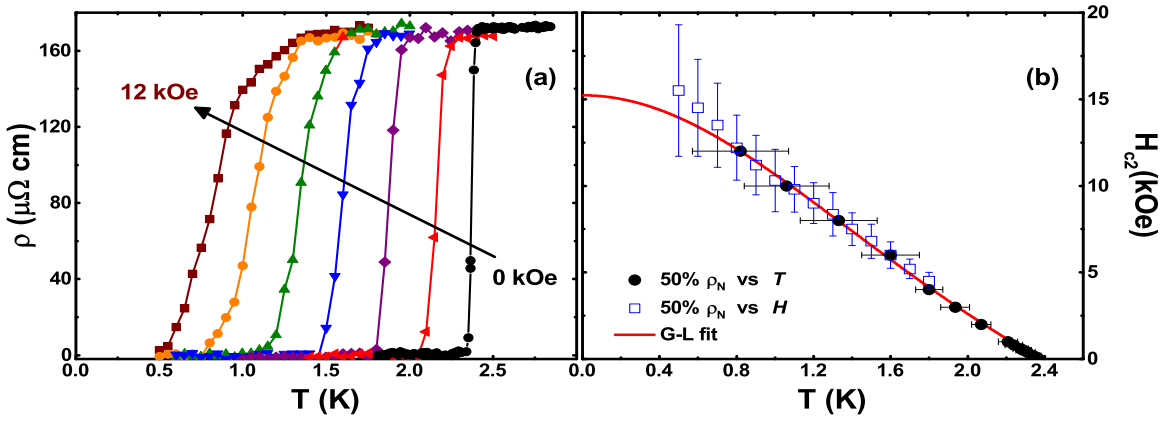

Figure 2. (a) Resistivity versus temperature in applied magnetic fields of 0 to 12 kOe in 2 kOe increments. (b) Upper critical field as a function of temperature, determined from ρ vs T measurements. The solid red line shows a fit using the Ginzburg-Landau (GL) model.

Muon Source, Rutherford Appleton Laboratory, United Kingdom. In the zero-field mode, the 64 detectors were placed in a longitudinal configuration and in the transverse-field mode, the spectrometer was rotated by 90°. The arc-melted button of $LaIr_3$ was ground to a fine powder and mounted on a high purity (99.995%) silver plate using GE varnish. The sample could be cooled to 100 mK using a dilution refrigerator. During the ZF measurements, the magnetic field at the sample position was held at less than 10 mOe by an active compensation system. The muon beam is deposited in the sample and the muons decay, with the emitted positrons counted in detectors placed either forward or backward of the initial muon spin direction. The time dependence of the asymmetry spectra were determined using $G_z(t) = [N_F(t) - \alpha N_B(t)]/[N_F(t) + \alpha N_B(t)]$, where $N_B(t)$ and $N_F(t)$ are the number of positron counts and the constant α can be calculated from a calibration measurement made in a transverse-field of 20 Oe. The ZF and TF-μSR data were analyzed using the WiMDA software [26].

3. Results and Discussion

3.1. Crystal structures and magnetization

Powder x-ray diffraction data confirmed the rhombohedral structure of the $LaIr_3$ sample with the space group 166 ($R\bar{3}m$) [22]. Fig. 1(a) shows the crystal structure of $LaIr_3$. The unit cell of $LaIr_3$ contains two distinct La sites (La1 and La2) and three Ir sites (Ir1, Ir2, and Ir3). The superconductivity in $LaIr_3$ was confirmed by the ZFC and FC susceptibility $\chi(T)$ data, as shown in Fig. 1(b). The low-field $\chi(T)$ data demonstrate a strong diamagnetic signal resulting from the Meissner effect below $T_C = 2.5$ K. The magnetization $M(H)$ curve at 2 K shown in the inset of Fig. 1(b) suggests type-II superconductivity. The lower critical field is found to be around 35 Oe at 2 K.

3.2. Resistivity

The temperature dependence of the electrical resistivity for $LaIr_3$ between 50 mK and 3.0 K in various applied magnetic fields is presented in Fig. 2(a). In zero field, the resistivity of $LaIr_3$ undergoes a superconducting transition at $T_C = 2.4$ K. It is to be noted that the resistivity in the normal state just above the transition temperature of our sample is higher (by a factor of 5) than the value reported by Haldolaarachchige *et al.* [22]. This could be due to micro-cracks in our sample. As expected, the superconducting transition becomes broader and the T_C shifts to lower temperature as the applied magnetic field is increased. The resistivity data were used to extract the upper critical field H_{c2}. The $H_{c2}(T)$ data at higher temperature and lower field can be fit using a standard Ginzburg–Landau (G-L) expression, $H_{c2}(T) = H_{c2}(0)\ [(1-t^2)/[(1+t^2)]$, where $t = T/T_C$ giving $H_{c2}(0) = 15.2(1)$ kOe. This is lower than the value reported by Haldolaarachchige *et al.* [22]. Near T_C, $\frac{dH_{c2}}{dT} = -6.6$ kOe/K, and using the Werthamer-Helfand-Hohenberg expression $H_{c2}(0) = -0.693\ T_C\ \frac{dH_{c2}}{dT}\Big|_{T=T_C}$ gave an upper critical field, $H_{c2}(0) = 10.9(1)$ kOe, which is also lower that the value obtained in Ref. [22]. Both the values of $H_{c2}(0)$ are also smaller than the weak-coupling Pauli-paramagnetic limit $H_P = 18.3T_C = 43.4$ kOe for $LaIr_3$.

3.3. Heat Capacity

Fig. 1(c) shows $C_P(T)/T$ in different applied magnetic fields. At 2.5 K, a clear anomaly is detected in $C_P(T)/T$ (in zero-field) implying bulk superconductivity, in agreement with the $\chi(T)$ data. In contrast to Ref. [22], the studied $LaIr_3$ sample show a very uniform transition temperature as obtained from various measurements, designating that approx. 2.4-2.5 K is the real bulk T_C. A second transition is observed in the heat capacity at 1.2 K, which is reminiscent of the second peak seen in the heat capacity of superconducting UPt_3 [27]. Our TF-μSR studies do not show any signature of the lower transition and additional studies are needed in order to identify the origin of the second transition. There is no difference between the ZF-μSR data at 0.09 and 4 K, and this supports the view that the second transition is not due to a magnetic impurity. In the presence of a 60 kOe field, the heat capacity jump is fully suppressed. The electronic and lattice heat capacity coefficients, γ and β, respectively, were calculated from the 60 kOe data, which is much higher than the upper critical field, by fitting $C_P(T)/T = \gamma + \beta T^2$, giving a Sommerfeld constant $\gamma = 15.3(1)$ mJ/(mol-K^2), $\beta = 0.56(1)$ mJ/(mol-K^4). Using this value of β ($= nN_A\frac{12}{5}\pi^4 R\Theta_D^{-3}$, where $R = 8.314$ J/mol-K), gives a Debye temperature $\Theta_D = 430(4)$ K. The estimated value of γ for $LaIr_3$ is very similar to that observed in $CaIr_2$ superconductor [19] and other Ir-based superconductors [17]. In the case of $LaIr_3$, the low value of the Sommerfeld constant may be due to the lack of f-orbitals near the Fermi surface. Using the value of heat capacity jump at 2.5 K, the dimensionless parameter $\Delta C_P/\gamma T_C \sim 1$ which is lower than the 1.43 expected in the BCS weak-coupling limit.

3.4. Superconducting gap structures

Figs. 3(a) and 3(b) present the time dependence of the TF-μSR asymmetry spectra around T_C while Fig. 3(c) shows the corresponding maximum entropy plots. The maximum-entropy (ME) method used to analyse the TF-μSR data is based on the Burg algorithm [28, 29] which draws on auto-regression prediction techniques. In contrast to Fourier transforms (FT), ME is useful for data collected over short-time windows and for noisy data, and does not suffer from truncation consequences, like FT sine wiggles. It provides a simultaneous interpretation

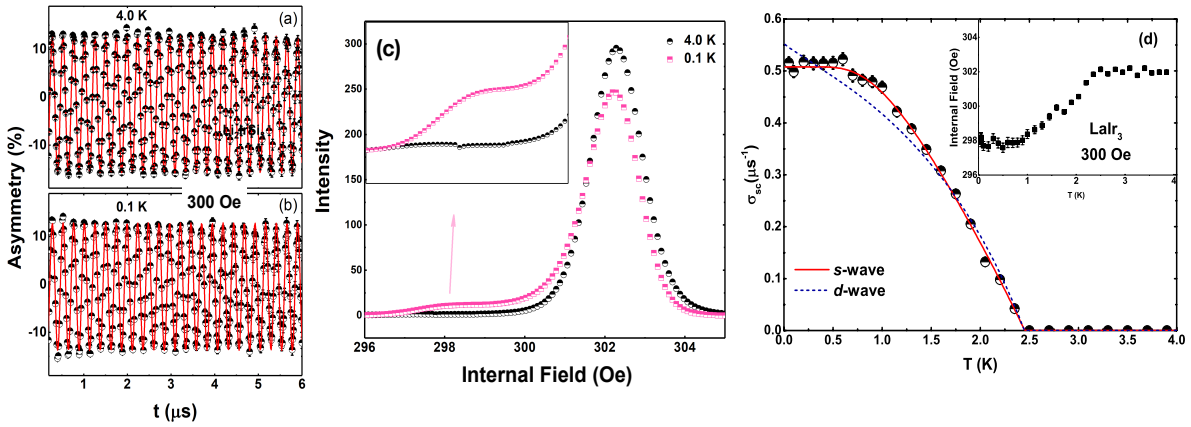

Figure 3. TF-μSR spin precession signals of $LaIr_3$ taken at $H = 300$ Oe. Time dependence asymmetry spectra (a) at 4.0 K, above T_C and (b) at 0.1 K, below T_C. The solid red lines indicate the fits to the data using Eq. 1. (c) Maximum entropy spectra (above and below T_C). Inset of Fig. 3(c) shows the part of field distribution originating from the vortex state. (d) Temperature dependence of the depolarization rate $\sigma_{sc}(T)$ where the solid line and dotted line are fits to the data employing an isotropic s-wave model and a d-wave model with line nodes, respectively, using Eq. 2. Inset of (d) shows the variation of the internal field with temperature.

of the asymmetry spectra from various detectors with distinct phases to produce a single frequency spectrum. At $T \geq T_C$, the muon depolarization is due to static nuclear moments and the resulting field distribution is centred near the applied field H. At $T \leq T_C$, the muon depolarization has a reasonable damping and the field distribution has two components, the first one close to the applied field H and the second shifted to a lower field value. The inset of Fig. 3(c) shows the portion of the field distribution arising from the vortex lattice. In order to investigate the superconducting order parameters and the pairing mechanism of $LaIr_3$ compound, we have carefully examined the TF-μSR data. Below T_C, the TF asymmetry spectra which decay due to the superconducting vortex state, could be fit by an oscillatory decaying function [31, 32, 33, 34, 35],

$$G_{z1}(t) = A_1 \cos(\omega_1 t + \Phi) \exp\left(\frac{-\sigma^2 t^2}{2}\right) + A_2 \cos(\omega_2 t + \Phi), \tag{1}$$

where A_1 and A_2 are the transverse field asymmetries, and ω_1 and ω_2 are the frequencies that emerge from the $LaIr_3$ sample and background silver holder respectively. Φ is the initial phase and σ is the total depolarization rate. The superconducting contribution σ_{sc} is calculated from $\sigma_{sc} = \sqrt{\sigma^2 - \sigma_n^2}$, where σ_n is the nuclear contribution which was obtained from the value of σ above T_C. The fitting to the lowest temperature TF data yields $A_1 \sim 25\%$ and $A_2 \sim 75\%$. In the TF-μSR fits shown in Fig. 3(d), A_2 is fixed and A_1 is allowed to vary. The inset of Fig. 3(d) exhibits the onset of superconductivity below T_C which is marked by a drop in the internal field. The temperature dependence of the magnetic penetration depth can be modelled using [30, 31, 34]

$$\frac{\sigma_{sc}(T)}{\sigma_{sc}(0)} = \frac{\lambda^{-2}(T, \Delta_0)}{\lambda^{-2}(0, \Delta_0)} = 1 + \frac{1}{\pi} \int_0^{2\pi} \int_{\Delta(T)}^{\infty} \left(\frac{\delta f}{\delta E}\right) \times \frac{E dE d\phi}{\sqrt{E^2 - \Delta(T, \Delta)^2}}, \tag{2}$$

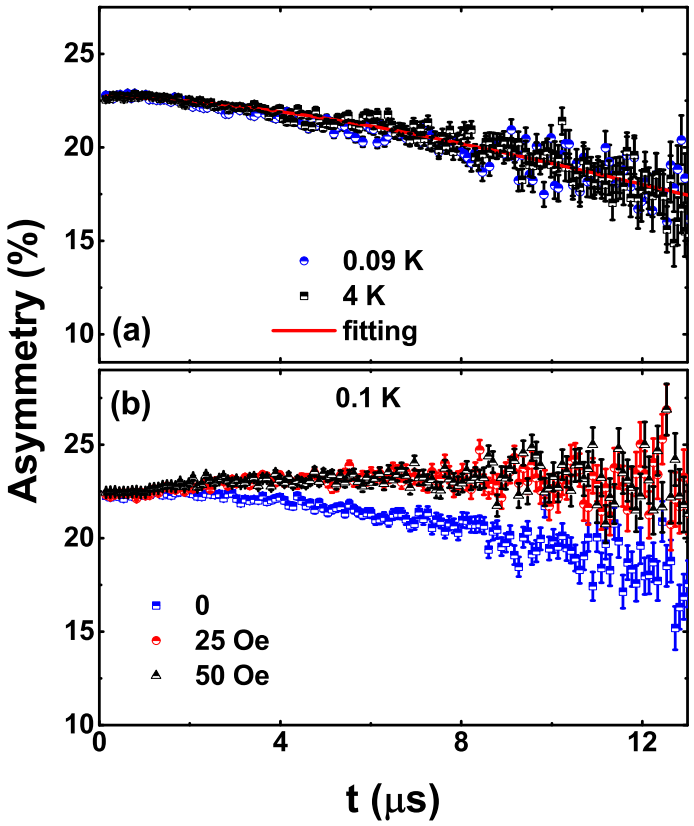

Figure 4. (Color online) (a) Time dependence of zero-field asymmetry spectra for $LaIr_3$ collected at 0.09 K (circles) and 4.0 K (squares). The lines are least squares fits to the ZF data made using Eqs. (4) and (5). (b) Longitudinal field asymmetry spectra taken at 0.1 K in the presence of various applied field H.

where $f = [1 + \exp(-E/k_BT)]^{-1}$ is the Fermi function, ϕ is the angle along the Fermi surface, and $\Delta(T, 0) = \Delta_0\delta(T/T)\mathrm{g}(\phi)$. The superconducting gap was approximated using $\delta(T/T_\mathrm{C}) = \tanh[1.82(T_\mathrm{C}/T - 1)]^{0.51}$ where $\mathrm{g}(\phi)$ gives the angular dependence of gap and ϕ is the polar angle for the anisotropy. $\mathrm{g}(\phi)$ is replaced with (a) 1 for an isotropic s-wave gap and (b) $|\cos(2\phi)|$ for a nodal d-wave gap [36, 37]. For $LaIr_3$, the $\lambda^{-2}(T)$ data can be modelled satisfactorily by employing an isotropic s-wave gap with a value of 0.35(1) meV. The gap to T_C ratio is found to be $2\Delta(0)/\mathrm{k}_BT_\mathrm{C} = 3.31(1)$, which lower than the value 3.56 expected from BCS theory. This suggests weak-coupling superconductivity in the case of $LaIr_3$ which is in agreement with the heat capacity data. TF-μSR measurements of $Mg_{10}Ir_{19}B_{16}$ reveal spin-singlet s-wave pairing, even though the lack of inversion symmetry and large SO coupling of $Mg_{10}Ir_{19}B_{16}$ should produce a mixed pairing state, likely with a large spin-triplet contribution [38]. TF-μSR data on La_7Ir_3 compound also reveal a gap with an isotropic s-wave pairing symmetry [39].

The muon depolarization rate below T_C is linked to the magnetic penetration depth, λ. In case of a triangular [40, 41, 42] lattice $\frac{\sigma_{sc}^2}{\gamma_\mu^2} = \frac{0.00371\times\phi_0^2}{\lambda^4}$, where $\phi_0 = 2.07 \times 10^{-15}$ Tm^2, is the flux quantum number and $\gamma_\mu/2\pi = 135.5$ MHz T^{-1}, is the muon gyromagnetic ratio. From the s-wave fit, we estimate that the magnetic penetration depth $\lambda(0) = 386(3)$ nm. London's theory [40] gives the relation between λ ($= \lambda_\mathrm{L}$) and other microscopic parameters

such as $\lambda_{\rm L}^2 = \frac{m^* c^2}{4\pi n_{\rm s} e^2}$, where $m^* = (1 + \lambda_{\rm e-ph})m_{\rm e}$ is the effective mass and $n_{\rm s}$ is the density of superconducting carriers, and hence one can calculate m^* and $n_{\rm s}$. The electron-phonon coupling constant $\lambda_{\rm e-ph}$ can be calculated using the Debye temperature, Θ_D, and $T_{\rm C}$ using McMillan's relation which is also valid in the weak-coupling limit [43, 44].

$$\lambda_{\rm e-ph} = \frac{1.04 + \mu^* \ln(\Theta_D/1.45T_{\rm C})}{(1 - 0.62\mu^*)\ln(\Theta_D/1.45T_{\rm C}) - 1.04}, \tag{3}$$

where μ^* is the Coulomb pseudo-potential. McMillan states [43] that $\mu^* = 0.1$ is confirmed for the nearly-free electrons metals such as zinc, and $\mu^* = 0.15$ is reasonable for most of the intermetallic superconductors [44, 45, 46, 47]. Furthermore, P. B. Allen [44] has stated that for conventional metals $\mu^* \leq 0.2$. Using $\mu^* = 0.15$ [22], we find $\lambda_{\rm e-ph} = 0.53$. Using the estimated value of $\lambda_{\rm e-ph}$ and $\lambda_{\rm L}(0)$, the superconducting carrier density is estimated to be $n_{\rm s} = 2.9(1) \times 10^{27}$ carriers m^{-3} and the effective-mass enhancement $m^* = 1.53m_{\rm e}$ for $LaIr_3$.

3.5. Zero-field muon spin relaxation

Fig. 4(a) shows the time dependence of ZF asymmetry spectra from $LaIr_3$ at $T \geq T_{\rm C}$ and $T \leq T_{\rm C}$. At $T \leq T_{\rm C}$, there is no change of muon asymmetry spectra compared to the spectra collected at $T \geq T_{\rm C}$, which suggests that time-reversal symmetry is preserved in $LaIr_3$. The ZF data for $LaIr_3$ can be modelled using the damped Kubo-Toyabe (KT) function [48, 49, 50, 51],

$$G_{\rm z2}(t) = A_0 G_{\rm KT}(t) e^{-\lambda t} + A_{\rm bg}, \tag{4}$$

where

$$G_{\rm KT}(t) = \left[\frac{1}{3} + \frac{2}{3}(1 - \sigma_{\rm KT}^2 t^2) e^{\frac{-\sigma_{\rm KT}^2 t^2}{2}}\right] \tag{5}$$

the Kubo-Toyabe function, models the change in asymmetry arising from static nuclear moments and λ, A_0, and $A_{\rm bg}$ are the electronic relaxation rate, initial sample asymmetry, and background asymmetry, respectively. The fits to the ZF data using Eqs. 4 and 5 give $\sigma_{\rm KT} = 0.041(5)$ μs^{-1} and $\lambda = 0.018(3)\mu$s^{-1} at 0.09 K and $\sigma_{\rm KT} = 0.041(1)\mu$s^{-1} and $\lambda = 0.013(2)\mu$s^{-1} at 4 K, while the fit parameters A_0 and $A_{\rm bg}$ are found to be temperature independent. Furthermore, the ZF-μSR spectra measured in longitudinal fields of 25 and 50 Oe at 0.1 K (Fig. 4(b)) revealed the decoupling of the muon spins from the static nuclear fields at the muon stopping sites.

Our ZF-μSR measurements indicate time-reversal symmetry is preserved in $LaIr_3$. A similar result is found in the Ir-based superconductor In $Mg_{10}Ir_{19}B_{16}$ [38], while in the case of La_7Ir_3, ZF-μSR data confirm that the superconducting ground state breaks time-reversal symmetry [39].

4. Summary

In summary, we have examined the superconducting gap structure and pairing symmetry of $LaIr_3$ using TF and ZF-μSR measurements. Bulk type-II superconductivity is observed in the susceptibility measurements with $T_{\rm C} = 2.5(1)$ K. Similar to UPt_3, two transitions are seen in the heat capacity data and the origin of the lower temperature feature remains unclear at this time. Transverse field-μSR measurements reveal a fully gapped s-wave type superconductivity

with the gap to T_C ratio, $2\Delta(0)/k_BT_C = 3.31$, compared to 3.56 (BCS value) suggesting weak-coupling superconductivity. Our ZF-μSR data do not reveal any sign of internal fields below T_C, which indicates that time reversal symmetry is preserved in $LaIr_3$. The results underline the need for further research into the properties of Ir-based intermetallic superconductors and especially those that have a noncentrosymmetric structure, where strong antisymmetric spin-orbit coupling could lead to unconventional superconductivity, perhaps with a mixed spin singlet-triplet pairing.
