ABSTRACT

Objectives Cholecystectomy is one of the most common surgical procedures performed worldwide to treat gallstone-related disease. Postcholecystectomy diarrhoea (PCD) is a well-reported phenomenon, however, the actual rate, predictive factors and mechanism of action have not been well determined. A systematic review was undertaken to determine the rate and predictive factors associated with diarrhoea in the postcholecystectomy setting.

Methods The review was conducted according to the Preferred Reporting Items for Systematic Review and Meta-Analysis Protocol. Databases searched included Medline, Embase, Pubmed, Cochrane and Google Scholar up to 29 September 2020. The inclusion criteria consisted of cohort studies or randomised trials which investigated the rate of PCD and predictive factors. Case reports, case series, conference abstracts and expert opinion pieces were excluded as were other systematic reviews as all the original articles from those reviews were included in this review. Papers that did not include PCD as a separate entity were excluded. Bias assessment was performed using the Newcastle-Ottawa Scale for cohort studies and the Cochrane risk of bias tool for randomised controlled trials as appropriate. Data were extracted by two authors (AF and JAA) and an overall rate of PCD was calculated. Predictive factors were also extracted and compared between studies.

Results 1204 papers were obtained and 21 were found to contain relevant information about PCD, including the number of patients developing diarrhoea, method of symptom assessment and time of onset postcholecystectomy. A pooled total of 3476 patients were included across the identified studies with 462 (13.3%) patients developing PCD. Possible predictive factors varied across all studies, with characteristics such as gender, age and weight of patients postulated as being predictive of PCD, with no agreement across studies.

Discussion PCD is therefore relatively common (13.3%). This has important implications for patient consent. Patients ought to be investigated early for bile acid diarrhoea in suspected PCD. More studies are required to determine the possible predictive factors for PCD. Limitations of the study included that most studies were not powered for calculation of PCD, and assessment methods between studies varied.

PROSPERO registration number CRD42019140444.

Strengths and limitations of this study

- This review focused on postcholecystectomy diarrhoea and all studies relating to postcholecystectomy symptoms were extensively investigated to extract all possible data.
- Possible predictive factors for postcholecystectomy diarrhoea were assessed which has not been extensively investigated.
- A wide variety of questionnaires was used to assess symptoms making it difficult to standardise postoperative symptoms between studies, and this relied heavily on patient recall thus opening up all the studies to recall bias.
- There was a generally low level of evidence as most studies were cohort studies.
- Patients were followed up for a variety of timeframes across the studies and thus it was difficult to standardise.

INTRODUCTION

Cholecystectomy is the gold standard treatment for symptomatic gallstone disease, which occurs in up to 22% of adults.1 The laparoscopic approach to this surgery is now well documented and accepted as standard practice, due to the significantly lower morbidity and mortality when compared with open surgery.2 As a result, its adaptation into a laparoscopic procedure has increased the frequency with which cholecystectomy is performed.3 4 Despite the notable benefits of cholecystectomy in treating gallstone-related disease, the postoperative course for a proportion of patients may be plagued by persistent or even new symptoms, including new-onset diarrhoea.5 This may be distressing for patients and have a significant impact on their quality of life.6 While it may be just a minor annoyance for some, others may well consider postcholecystectomy diarrhoea (PCD) to be a social disability.7 8

The actual incidence of PCD is unknown, though there is a wide range reported in the literature (2.1%–57.2%).9 10 Furthermore,
implicated mechanisms in the onset of this condition remain significantly under-investigated.

At present, there are two main theories regarding the mechanism. The first suggests changes in the oroacal and colonic transit times secondary to increased enterohepatic circulation brought on by removal of the gallbladder. The second mechanism is less well defined and involves the potential role of bile acids in causing diarrhoea. This mechanism has been proposed in idiopathic bile acid diarrhoea, where there is interruption of a negative feedback loop which controls bile acid synthesis. The working theory is that removal of the gallbladder, thus removing a bile storage system, will lead to over synthesis of bile acids by interrupting the same negative feedback loop, thus causing diarrhoea by overloading the uptake mechanisms in the terminal ileum. 63.5% of patients who develop diarrhoea after cholecystectomy develop bile acid diarrhoea. The aim of this systematic review is to analyse published literature in order to assess the incidence of post-cholecystectomy diarrhoea. Potential preoperative factors which may help to predict the development of PCD will also be examined. Recommendations for future direction of research shall be made, if appropriate.

METHODS

The review was registered on PROSPERO. A literature search was performed on Pubmed, Embase and Medline, Cochrane, Google Scholar using the keywords ‘post-cholecystectomy’, ‘postoperative’, ‘cholecystectomy’, ‘diarrhoea’ and ‘predictive factors’. There were no language limitations. The last search date was 29 September 2020. There were no restrictions to the year of publication. The search strategy is outlined in figure 1.

The inclusion criteria were cohort studies or randomised controlled trials (RCTs) which investigated the rate of PCD and predictive factors for this condition. Case reports, case series, conference abstracts and expert opinion pieces were also excluded. Systematic reviews were also excluded as all the original articles from those reviews were included in this review. Studies pertaining to persistent symptoms after laparoscopic cholecystectomy, that is symptoms present preoperatively, rather than new symptoms were also excluded.

Data were extracted from the studies independently and entered into an electronic database. The results were subsequently collated. Data extracted included: patient numbers, age, gender, type of study, indication for surgery, preoperative symptoms, postoperative symptoms, predictive factors. The primary endpoint was to identify the rate of PCD and the secondary endpoint was to identify potential predictive factors.

The systematic review was written according to Preferred Reporting Items for Systematic Reviews and Meta-Analyses guidelines. Risk of bias assessment was
performed using the Newcastle-Ottawa Scale for cohort studies and the Cochrane risk of bias tool for RCTs as appropriate.\textsuperscript{15, 16} The papers were classified according to the Oxford OCEBM levels of evidence.\textsuperscript{17}

Two independent reviewers (AF and JAA) performed the literature search and reviewed papers for inclusion to ensure the criteria were met. Any differences were resolved by mutual consent. All data extraction was also performed independently by the same two authors.

**Patient and public involvement**

There was no patient or public involvement in this study.

**RESULTS**

**Selected studies**

A total of 1204 papers were identified in the initial search which was reduced to 947 after removal of duplicates. After screening by title and abstract 45 papers were initially considered. Full-text review of these papers revealed that 17 were relevant, that is describing new-onset PCD. The reference lists of the chosen articles were also screened, and a further four papers were found to fit the inclusion criteria. This is shown in figure 1. Two articles had to be excluded as full text could not be obtained despite contacting the authors.

**Characteristics of included studies**

Most of the studies included were cohort, longitudinal, case-control or cross-sectional studies, of which 11 were prospective and 8 were retrospective. Two studies were RCTs, one of which was an RCT comparing laparoscopic cholecystectomy and cholecystectomy via minilaparotomy, however, one of the reported outcomes was diarrhoea and therefore merited inclusion into this review.\textsuperscript{18} The other RCT was to investigate the effect of Rowachol once again meriting including into the study.\textsuperscript{10} The authors also assess symptom clusters including diarrhoea, the Oxford OCEBM levels of evidence.\textsuperscript{17} The reference lists of the chosen articles were also screened, and a further four papers were found to fit the inclusion criteria. This is shown in figure 1. Two articles had to be excluded as full text could not be obtained despite contacting the authors.

**Quality assessment and risk of bias**

The Newcastle-Ottawa assessment scale for cohort studies was selected for a risk of bias assessment and adapted to included observational studies. An adaptation of the tool is provided in online supplemental table 1. Patients who underwent laparoscopic cholecystectomy were assessed via a combination of structured interviews and self-reporting. However, as shown in table 1, patient follow-up in a number of studies was not adequate as several patients were not followed up for longer than 3 months. Consequently, this may introduce high levels of bias. Furthermore, lack of a control group in the majority of studies also predisposes to bias in the results. The full risk of bias assessment can be found in online supplemental table 1. It was not possible to check the heterogeneity of studies due to lack of data, as CIs were not available.

**Level of evidence**

The level of evidence was assessed as per the Oxford criteria for Evidence Based medicine. As most of the studies were cohort studies, and a large number of them were retrospective in nature, the general level of evidence was low, classed at 3 or 4. More detail is shown in online supplemental table 1 and 2.

**Demographics**

Demographic data were not routinely available in all studies. However, from those that reported it there were 2250 women and 787 men. Five of the included studies did not provide this information. The age range of patients across the studies was 18–85. One thousand eight hundred and fifty-five cholecystectomies were performed laparoscopically and 378 were open, though once again there were 5 studies where this information was not provided.

**Rate of PCD**

A total of 3476 patients were included across all the studies with 462 (13.3\%) patients developing PCD, though the rates in the studies vary between 2.1\% and 57.2\%. The greater majority of patients were assessed in the first 3–6 months postoperatively, though there is also a large amount of variation in the timing of PCD as patients were assessed between 6 weeks up to 4 years postoperatively. These are outlined in table 1. There were not enough data to be able to calculate median time to development of PCD postcholecystectomy.

**Predictive factors for PCD**

Several potential risk factors for PCD were identified. Age less than 45 or 50 was mentioned in two studies, as was a high body mass index (BMI). One study suggested that it was commoner in men while two others suggested it was commoner in women. A further two studies associated PCD development with preoperative heartburn or gastritis, while two others still related this to high fat intake. There is lack of consistency in the predictive factors identified in all studies, some studies found no potential predictive factors including sex, age and preoperative symptoms.

**DISCUSSION**

Diarrhoea is one of the most reported postoperative symptoms after cholecystectomy, whether this is persistent or new postoperatively, though it varies significantly between studies.\textsuperscript{1} The first mention of this in the literature as a common postoperative sequela is due to Ros and Zambon\textsuperscript{19} who conducted a prospective cohort study to assess postcholecystectomy symptoms. The postoperative assessment took place 2 years after surgery and only 93 of the original 124 patients were available. Eight of these patients reported postoperative loose stools and watery diarrhoea.\textsuperscript{19} In subsequent studies, patients with postcholecystectomy were compared with patients having...

BMI, body mass index; CBD, common bile duct; EORTC-QLQ-C-30, European organisation for the research and treatment of cancer quality of life questionnaire; EQ-5D, Euro-qual 5D; GIQLI, gastrointestinal quality of life; HADS, Hospital Anxiety and Depression Score; PCD, postcholecystectomy diarrhoea; SCL 90 R, symptom checklist 90 revised; SF-36, short form 36.
other surgeries such as inguinal hernia, laparoscopic sterilisation and hysterectomy, and bowel habit assessed and compared. In some cases, a proportion of patients who developed diarrhoea resolved after a few weeks or months. The question of whether laparoscopic or open cholecystectomy affected the postoperative symptoms was explored. McMahon et al. performed a multicentre RCT to assess the symptomatic outcome between mini-laparotomy and laparoscopic cholecystectomy. However, no change when change is not always present. Predictive factors identified for PCD varied widely across studies that assessed such factors. Fisher et al. concluded that it was associated with being men, younger than 50 and having a high BMI, also confirmed by Yueh et al. and Jasim et al. (though in this case the age limit was less than 40 years old) while Del Grande et al. associated this with prior gastrointestinal symptoms, though they did not define which ones. Mertens et al. clarified this further by stating that it was preoperative flatulence and heartburn which predicted postoperative symptoms including diarrhoea. Yueh et al. also found that not following a low-fat diet could be associated with PCD. Talseth et al. study
found that PCD was more common in patients having cholecystectomy for biliary colic, while Manriquez et al.22 asserted that it was more common in patients having cholecystectomy for asymptomatic cholelithiasis.22–41 On the other hand, Kim et al.42 identified no predictive factors including age, BMI, sex, American Society of Anaesthesiologists score, preoperative Endoscopic retrograde cholangiopancreaticography (ERCP), comorbidities, difficult laparoscopic cholecystectomy, open conversion or pathology.10

Wanjura et al.22 found that several factors were predictive of worse gastrointestinal symptoms after cholecystectomy, including female gender, CBD stones or pancreatitis and gallstone pain as an indication for surgery, however, did not particularly relate this to diarrhoea.42 Kim et al.23 also said that gastritis was a preoperative predictive factor for developing post cholecystectomy symptoms, however, once again did not specifically relate this to diarrhoea.23

Definition and recommendations for consent and investigation

The difference in prevalence of diarrhoea across the studies could be attributed to factors such as study design, follow-up length, questionnaire wording (as some studies used non-validated questionnaires), issues with patient recall and definitions of diarrhoea. Unfortunately, most of the studies in this review are not powered specifically to find the rate of PCD, but investigate postcholecystectomy symptoms in general, and in fact most studies focused on dyspeptic symptoms and pain. Some studies were also excluded as they did not specify whether the diarrhoea reported was new onset after cholecystectomy. There has been no standardised definition of PCD and indeed most of the studies do not specify how they defined ‘diarrhoea’ in the postoperative period. We feel that a standard definition would be helpful in the investigation of PCD. From the above, we can attempt to define PCD as ‘the development of diarrhoea, more than three times a day for more than 4 weeks, post-cholecystectomy’. Investigations for PCD should include basic blood and stool tests, followed by endoscopic examination and 75SeHCAT tests to investigate for inflammatory bowel disease and bile acid diarrhoea respectively.43

Possible therapies for PCD

If it is indeed bile acid diarrhoea, a bile acid sequestrant such as colestyramine could help symptoms.15 However, in other patients once other causes have been excluded including inflammatory bowel disease, other symptomatic treatments are required such as loperamide or dietary modifications.44

Strengths and limitations

The major strength of this review is that we considered the possible predictive factors for the development of PCD. We also looked at all studies involving postcholecystectomy symptoms and if data could be extracted regarding PCD this was also done, thus adding more numbers to the study and providing a more accurate picture of the actual PCD rate. It should also inform the consent process prior to surgery, as currently patients are not always informed that this is a possibility, and may significantly affect their quality of life.45

However, there were some methodological limitations. There was no standardisation between studies in terms of follow-up times, as well as questionnaire use. Some authors also used non-validated questionnaires thus making reproducibility difficult. Questionnaires are heavily based on patient recall and there is therefore an element of recall bias in all these studies. Almost all the studies were cohort studies, thus the lack of control group contributed to a low general level of evidence. These limitations could be the reason behind the wide variation of PCD rates across the studies.

Implications for future research

Larger prospective studies are required to determine the exact rate of PCD and possible predictive factors. It would also be interesting to see how many patients are investigated for PCD using real time clinical data, to investigate how this issue is being handled outside of study protocols. A useful method of keeping better track of such patients is setting up a national registry which could be run by trainees. Another potential method of investigating this would be to set up a large, prospective, national study of patients having cholecystectomy for various reasons, including cholelithiasis, polyps and cancer, and investigate possible predictive factors such as BMI, smoking, sex, age and comorbidities. The quality of life (QOL) preoperatively and postoperatively could also be assessed, especially the difference in QOL between those who develop PCD and those who do not. Further work is also required to determine the exact mechanism behind its development, potentially looking further into the role of FGF19 and C4 levels, and their relationship to bile acid synthesis after cholecystectomy.

CONCLUSION

PCD is becoming an increasingly recognised issue with an overall incidence of around 13.1%. However, no well-defined predictive factors can be elucidated. It is often not recognised as a problem as patients are not routinely followed up. It is also a significant burden on patients. The mechanism behind its development also needs to be investigated further, though the role of bile acids in this is also becoming more defined. Patients need to be more informed about the possibility of this occurring as part of the consent process preoperatively and in the postoperative period more support needs to be offered to patients in the investigation and diagnosis process.
