A bidirectional WDM-PON Free Space Optical (FSO) system for fronthaul 5G C-RAN Networks

Fady El-Nahal, Tianhua Xu, Member, IEEE, Dokhyl AlQahtani, Student Member, IEEE, and Mark Leeson, Senior Member, IEEE

Abstract—High-speed cellular technologies require low-latency and high-capacity optical networks. The Centralized Radio Access Network (C-RAN) architecture offers a cost-effective solution for mobile network deployment. To maximize flexibility and minimize deployment costs of fronthaul networks, we propose a hybrid bidirectional fronthaul C-RAN topology based on Wavelength Division Multiplexing (WDM) passive optical networks (PONs) and free space optical communication (FSO). The wavelength reuse scheme utilized here relies on reflective semiconductor optical amplifiers (RSOAs) to reduce cost and increase capacity. The system was demonstrated for reflective semiconductor optical amplifiers (RSOAs) to reduce cost and increase capacity. Index Terms—Free Space Optics (FSO), Centralized Radio Access Network (C-RAN), Passive Optical Network (PON).

1. Introduction

The demand for high-speed data services is increasing dramatically as a result of the popularity of cloud computing, big data processing, and high-definition video broadcasting. Passive optical network (PON) and wireless access systems would be the most promising options for providing cost-effective last-mile access high-speed data to end users. WDM-PON is an excellent candidate for a future broadband access network since it can achieve greater capacity access and provide nearly infinite bandwidth to each end node. However, the PON system may not be the best option in areas where fiber installation is costly owing to geographical limitations. Hence, free-space optical communication (FSO) technology can be merged with it to overcome the problem [1]–[3].

icated wavelength for each user and a speed of 25 Gbps or more has been suggested [14]. One of the major technologies for WDM-PON is colorless ONUs with tunable transceivers [15]. A 25 Gbps colorless ONU with a reflecting electro-absorption modulator and a semiconductor optical amplifier for 5G fronthaul has been investigated in [16].

The development and maintenance of a stand-alone PON system may not be practical for the deployment of fronthaul/backhaul networks, especially in dense metropolitan areas, because fiber deployment is not always practicable or expensive in every context. PON and FSO can be integrated to reduce the cost of the fronthaul network. FSO fronthaul links offer a cost-effective alternative to fiber-based fronthaul, allowing a significant decrease in deployment costs [10].

II. RELATED WORK

Various designs and technologies have been considered for fronthaul deployment. According to [17], a moderate deployment of C-RAN, in which some BBU functions are relocated to the cell site to reduce the bandwidth requirements of the fronthaul segment, is preferred over a completely centralized model in which all BBU processing is performed at the central site. High-speed PON technologies, which support 5G wireless with high capacity, low latency, low power per bit, and low cost, were explored in [18]. The authors in [19] investigated the advantages of PON, which features superior bandwidth management and fiber sharing resources, over PtP fiber for fronthaul deployment. In [20], a coherent WDM-PON system with a DP-16 quadrature amplitude modulation (DP-16QAM) transceiver was investigated to meet the aggregate capacity demands of 5G-and-beyond cellular networks. Fronthaul and backhaul network costs could be reduced considerably by employing PONs, according to [21]. A comparison of fiber-based backhaul systems with existing fiber-to-the-home solutions is presented in [22]. The economic effects of fiber and microwave backhaul systems for low and high wireless traffic requirements were investigated in [23]. In [24], the optimal deployment costs associated with different deployment scenarios and different fronthaul technologies, including Analog and Digital Radio over Fiber were analyzed. A cost-efficient GPON backhaul deployment for small-cell networks compared to typical Ethernet-based PtP fiber backhauling was investigated in [25].

There has been extensive research on FSO-based systems for deployment as access networks, both for fronthaul and backhaul in recent years [26]. FSO could minimize fronthaul network deployment costs, particularly in cases where fiber cannot be economically deployed [1], [27]. An FSO link was deployed and evaluated in [28] for fiber protection in PON distribution. In [10], a low-cost hybrid PON-FSO-based fronthaul solution for 5G C-RAN architecture was investigated for deployment in congested urban areas. In [29], PON technology was utilized for a hybrid fiber/FSO fronthaul wireless scenario in order to increase flexibility and reduce deployment costs. A full-duplex architecture for the transmission of ultrawideband (UWB) signals over the FSO network that offers the benefits of installation simplicity and mobility was presented in [30]. Dahrouj et al. [31] have demonstrated that a radio frequency and FSO system can be combined to create a robust and cost-effective transport network infrastructure. All-optical

Fig. 1. The WDM FSO architecture
generation and transmission of multiple UWB signals to radio access units over an FSO link was demonstrated in [6] using a centralized frequency comb source.

A full C-RAN design will most likely use fiber for the fronthaul network, although PON, millimeter/microwave, and FSO-based technologies are potential options for a partial C-RAN network. Fronthaul deployment scenarios depend on several factors, including spectrum license fees, deployment time, equipment availability, and quality of service desired. As a result, PON and FSO technologies could be merged to enable fronthaul connection to diverse networks in crowded urban environments [3], [10].

WDM PON can be made more cost-effective by utilizing a wavelength reuse scheme, where no optical sources are required for upstream transmission. The upstream and downstream channels of these systems utilize the same wavelength to maximize wavelength utilization. A wavelength signal is remodulated with uplink data and then transmitted back as an uplink signal [32]. Reflective semiconductor optical amplifiers (RSOAs) are widely used in WDM-PONs utilizing wavelength reuse. Owing to its optical gain, integration capability, and wide optical bandwidth, the RSOA can be used as an uplink colorless transmitter and modulator [33].

There is an ever-increasing demand for higher bandwidth in optical communication networks. Therefore, it is imperative that modulation speeds be improved. Traditionally, fiber optic networks have used dense wavelength division multiplexing (DWDM) to transmit separately On-off keying (OOK) signals. As a result, the restricted total optical spectrum, coupled with the low bit rates achievable per optical signal, limits the bandwidth available overall. There has been a growing interest in wideband modulation schemes which utilize higher spectral efficiency modulation and multi-tone carriers, such as optical orthogonal frequency-division multiplexing (OFDM) [34], [35]. This is a multicarrier, high-data-rate transmission method used primarily in wireless communications. The OFDM system utilizes several lower-rate orthogonal subcarriers in order to transmit the total high data rate. It is possible to modulate the orthogonal subcarriers of an OFDM signal in a variety of ways, such as QAM.

Here we have evaluated a novel hybrid bidirectional PON-FSO architecture based on wavelength reuse for 5G C-RAN fronthaul, in which fiber would be laid as long as it is cost-effective and practical. Then FSO links would be utilized to expand this access to several sites and eventually interconnect mobile users. The wavelength reuse scheme utilized here relies on RSOAs to reduce cost and increase capacity since no optical source is needed for upstream transmission. Here, 20 Gbps OFDM and 5 Gbps OOK WDM signals can be transmitted over a 20 km SMF and 700 m FSO link for downstream and upstream traffic, respectively. The proposed hybrid PON-FSO system provides low-cost transmission of high-data-rate signals, mobility, and shortened deployment times.

III. WDM-FSO ARCHITECTURE
The proposed bidirectional WDM-PON FSO architecture is shown in Fig. 1, where the BBU is located at the CO, and the RRHs are situated in the small cells (ONUs). The source used in this architecture consists of a multi-wavelength comb source, including a DeMux and Mux stage, as well as broadband modulators. The UWB signal is generated by integrating multiple optical wavelengths, each modulated by an RF OFDM input. The OFDM signals in this work utilized 16-QAM modulation, to provide better spectral efficiency and higher transmission rates than OOK. OFDM also provides FSO systems with a transmission method that offers resilience in the presence of multipath fading, frequency selective fading, and intersymbol interference (ISI), thus increasing their transmission range. Here, the input data are encoded into a serial stream of 16-QAM symbols using a QAM sequence encoder (4 bits per symbol). This input serial data stream is then converted into a parallel stream of OFDM symbols. Following the placement of data into several OFDM symbols, these are assigned to orthogonal subcarriers and this QAM-OFDM signal is used to modulate the optical WDM signal. The OFDM symbols must be converted from the frequency domain into the time domain to be transmitted along an optical carrier. This is achieved by applying an inverse fast fourier transform (IFFT) to each of them. In each WDM channel, a non-return to zero (NRZ) $2^{23} – 1$ pseudorandom bit stream (PRBS) sequence has been generated with a data rate of 40 Gbps. Using an OFDM modulator with 512 subcarriers and 1024 FFT points, a data rate of $(512/1024) \times 40 = 20$ Gbps was generated from this signal. After the IFFT, a cyclic prefix of 100 was added to each OFDM symbol to avoid ISI. The proposed architecture had $N = 16$ wavelengths spanning from 1556.96 nm to 1550.92 nm (192.55 THz to 193.3 THz) with a transmission capacity of 320 Gbps. To minimize ISI, cosine roll-off filters were used to shape pulses before transmission. The OFDM

modulated signal was up-converted from the electrical to the optical domain using a Mach-Zehnder modulator (MZM). The optical signal was combined with other WDM signals using a WDM MUX, amplified using an Erbium-doped fiber amplifier (EDFA), and transmitted over the single-mode fiber (SMF). The WDM signals were subsequently separated with a WDM DeMux, before being sent over FSO links to the ONUs. As each WDM signal was received at the ONU, it was split by 3 dB optical splitters and half of the OFDM modulated signal was then sent to an OFDM receiver. At the receiver, a PIN photodetector (PD) converted each WDM signal into an electrical signal, which was amplified by an electrical amplifier. A quadrature demodulator was then used to down-convert the amplified signal and recover it. An OFDM demodulator then retrieved the QAM symbols and a QAM sequence decoder converted the received symbols into bits based on the number of bits per symbol.

For the up-link, an RSOA remodulated the other half of the downstream OFDM-modulated signal to generate a 5 Gbps NRZ OOK PRBS $2^{23} - 1$ upstream signal. Since the seeding power of an RSOA significantly affects its modulation characteristics, a variable optical attenuator (VOA) was utilized to maintain the power at the input of the RSOA at a level where the RSOA operated in the gain saturation region. The OOK signals were transmitted as upstream data via FSO links and combined with a WDM Mux before being sent via SMF back to the CO. There, they were separated by a WDM DeMux and each OOK signal was detected directly by a PIN receiver.

FSO is mainly impacted by atmospheric attenuation and random variation of signal intensity and phase caused by atmospheric turbulence, referred to as intensity scintillation [6]. Various FSO statistical channel models are used to estimate the turbulence of an optical signal, for example the Log-normal model, K model, Negative exponential model, Gamma-Gamma model, and Log-normal Rician model [28]. The Gamma-Gamma FSO model is commonly used to simulate atmospheric turbulence and attenuation over a broad range of turbulence conditions [10].

In this case, the probability density function of the normalized light intensity $I$ is given by [36]:

$$P(I) = \frac{2(\alpha \beta)^{\frac{\alpha + \beta}{2}} I^\frac{\alpha + \beta}{2} - 1}{\Gamma(\alpha) \Gamma(\beta) \left(2\sqrt{\alpha \beta I}\right)^{\frac{\alpha + \beta}{2}}} \left(\frac{0.49\sigma_R^2}{\left(1 + 1.11\sigma_R^2\right)^{\frac{1}{2}}} \right) - 1$$ (1)

$$\alpha = e^{p \left[\frac{0.49\sigma_R^2}{\left(1 + 1.11\sigma_R^2\right)^{\frac{1}{2}}} \right] - 1}$$ (2)

$$\beta = e^{p \left[\frac{0.51\sigma_R^2}{\left(1 + 0.69\sigma_R^2\right)^{\frac{1}{2}}} \right] - 1}$$ (3)

$\alpha$ and $\beta$ are the numbers of small and large turbulence cells, $\Gamma(\cdot)$ is the Gamma function and $K_{\alpha-\beta}(\cdot)$ is a modified Bessel function of the second kind.

The intensity variance $\sigma_R^2$, which directly depends on the magnitude of atmospheric turbulence, is given by:

$$\sigma_R^2 = 1.23C_n^2 k^{\frac{2}{3}} z^{\frac{11}{12}}$$ (4)

where $C_n^2$ is the refractive index structure parameter with value ranges from $10^{-13}$ $m^{-1/2}$ for strong turbulence to $10^{-17}$ $m^{-1/2}$ for weak turbulence, $k = \frac{2\pi}{\lambda}$ is the optical wavenumber and $z$ is the range of the FSO link. The quasistatic model, also known as the frozen channel model, is used to calculate channel time fluctuations. According to this model, channel fading remains the same over the course of a frame of symbols (coherence time), changing between frames to a new value.

IV. RESULTS AND DISCUSSION

The Optiwave simulation tool for optical system design was used to assemble and evaluate the WDM-PON FSO architecture [37]. Table I lists the parameters used in the simulation of the system. Bit error rate (BER) versus optical signal-to-noise ratio (OSNR) measurements were carried out to evaluate the performance of the bidirectional WDM-PON.
FSO architecture. Fig. 2 and Fig. 3 show the BER curves for the OFDM downstream and OOK upstream traffic, respectively, using three selected wavelength signals: 1556.96 nm (λ₁), 1554.13 nm (λ₈), and 1550.92 nm (λ₁₆) over different lengths of SMF (10 and 20 km), while keeping the FSO range fixed at 500 m. It is evident from the downlink results in Fig. 2 that the BER improves as the OSNR increases, as is expected. In addition, it can be seen that increasing the SMF range generally has a minimal impact on the BER performance. This can be attributed to the fact that OFDM is resilient to fiber impairments, which increase with the expansion of PON’s reach. Moreover, it is obvious that the BER performance

Fig. 7. BER versus FSO Link range plots for downlink and uplink

degraded gradually as the WDM signal moved to a shorter wavelength position. For example, at OSNR = 32 dB, the BER increases from $4.1 \times 10^{-5}$ for $\lambda_1$ to $2.5 \times 10^{-4}$ for $\lambda_{16}$ after 10 km of SMF and from $8.1 \times 10^{-5}$ for $\lambda_1$ to $1.7 \times 10^{-3}$ for $\lambda_{16}$ after 20 km of SMF respectively.

For the uplink, however, it is evident from Fig. 3 that the BER varies slightly with increasing OSNR for each WDM signal, which can be predicted since the RSOA operates in the gain saturation region. Table II lists the parameters of the RSOA used here. The BER performance, however, has worsened with the increase in PON reach from 10 to 20 km, as expected. As PON reach increases, fiber impairments significantly impact data-modulated optical signals, especially OOK signals, compared with OFDM signals, resulting in poor BER performance.

The performance of various WDM signals has been further evaluated using constellation and eye diagrams obtained at various SMF ranges and a fixed FSO range of 500 m. Fig. 4 displays the constellation diagrams of various downstream WDM signals ($\lambda_1$, $\lambda_8$, and $\lambda_{16}$) obtained at 10 km and 20 km of SMF. There are slight variations in the constellations of $\lambda_1$ and $\lambda_8$ as the length of SMF is extended. However, the constellation for $\lambda_{16}$ has been slightly distorted by increasing the length of SMF from 10 to 20 km. The results confirm that the BER performance degrades with the decreasing wavelength of the WDM signal. Fig. 5 depicts the eye diagrams of different upstream WDM signals obtained at 10 km and 20 km of SMF lengths. It is shown in Fig 5 that as the length of the SMF increases, the opening of the eyes decreases, indicating that the BER performance is declining.

Fig. 7 shows the BER performance of the downstream and upstream FSO traffic over various FSO link ranges while keeping the SMF range fixed at 20 km. It is clear from Fig. 7 that as free space transmission distance increases, the BER performance of the system degrades. At the forward error correction (FEC) limit of $\sim 3.8 \times 10^{-3}$ that defines the maximum BER level at which FEC can be used reduce BER to a tolerable level, for instance, the WDM signals 1556.96 nm ($\lambda_1$), 1554.13 nm ($\lambda_8$), and 1550.92 nm ($\lambda_{16}$) could reach nearly 890 m, 880 m, and 700 m downstream, and 950 m, 960 m, and approximately 1000 m upstream, respectively. Accordingly, the FSO signal was capable of bidirectional transmission over 700 m depending on the wavelength. As downstream and upstream signals travel on different paths

The performance of various WDM signals has been further evaluated by using constellation and eye diagrams derived at different FSO reach points. Fig. 6 and Fig. 8 show the constellation and eye diagrams of different downstream and upstream WDM signals ($\lambda_1$, $\lambda_{8}$, and $\lambda_{16}$) at different FSO ranges, respectively. As can be seen from the results, the constellation and eye diagrams have been significantly distorted by increasing the range of the FSO link from 500 to 1000 m. For the downlink, it is evident that the effect of expanding the FSO range is more significant at shorter wavelengths ($\lambda_{16}$) than at longer wavelengths ($\lambda_{1}$). The results indicate that longer wavelength downstream traffic can achieve better BER performance and an extended range than shorter wavelengths. This can be explained by the fact that at shorter wavelengths, the attenuation resulting from atmospheric absorption increases slightly, degrading the performance of the system [38]. However, for upstream traffic, the BER performance of the different wavelengths is comparable even shorter wavelengths have a slightly better performance than longer ones. This is clear from the BER results in Fig. 3 and 7 and the eye diagram results in Fig. 5 and 8. This can be explained by the gain characteristics of the RSOA [39]. Moreover, the results demonstrate that the upstream signals are relatively unaffected by the Rayleigh backscattering noise caused by the downstream signals. This has been achieved by operating the RSOA in the gain saturation region to remove the downlink modulation on the seeding wavelength.

V. CONCLUSION

We have evaluated a hybrid fronthaul C-RAN topology based on WDM-PONs and free space optics (FSOs) to accommodate the aggregate capacity demands of high-speed cellular networks. The PON-FSO system utilizes a centralized multi-wavelength comb source and direct detection, where a wavelength reuse scheme based on wavelength-seeded RSOAs is employed to reduce the cost of the architecture. On the downlink, an OFDM-modulated signal was transmitted, while on the uplink, an RSOA at the ONU re-modulated the downstream OFDM signal into an OOK signal. As shown by the BER measurements of WDM signals, the hybrid PON-FSO system may achieve 20 Gbps downstream and 5 Gbps upstream traffic for each wavelength over a 20 km SMF and 700 m free space transmission distance. The results demonstrate that the proposed PON-FSO topology offers a great alternative to fiber-based optical interconnect in P2P links in PONs, allowing high data rates in both directions.
