(Dated: November 15, 2011)

Pattern formation in microbial colonies of competing strains under purely space-limited population growth has recently attracted considerable research interest. We show that the reproduction time statistics of individuals has a significant impact on the sectored patterns. Generalizing the standard Eden growth model, we introduce a simple one-parameter family of reproduction time distributions indexed by the variation coefficient \(\delta \in [0, 1]\), which includes deterministic (\(\delta = 0\)) and memoryless exponential distribution (\(\delta = 1\)) as extreme cases. We present convincing numerical evidence and heuristic arguments that the generalized model is still in the KPZ universality class, and the changes in patterns are due to changing prefactors in the scaling relations, which we are able to predict quantitatively. At the example of S. cerevisiae, we show that our approach using the variation coefficient also works for more realistic reproduction time distributions.

I. INTRODUCTION

Spatial competition is a common phenomenon in growth processes and can lead to interesting collective phenomena such as fractal geometries and pattern formation. This is relevant in biological contexts such as range expansions of biological species or growth of cells or microorganisms, as well as in social contexts such as the dynamics of human settlements or urbanization. These phenomena often exhibit universal features which do not depend on the details of the particular application, and have been studied extensively in the physics literature.

Our main motivating example will be growth of microbes in two dimensional geometries, for which recently there have been several quantitative studies. In general, the growth patterns in this area are influenced by many factors, such as size, shape and motility of the individual organism, as well as environmental conditions such as distribution of resources and geometric constraints, which in turn influence the proliferation rate or motility of organisms. We will focus on cases where active motion of the individuals can be neglected on the timescale of growth, which leads to static patterns and is also a relevant regime for range expansions. We further assume that there is no shortage of resources, and growth and competition of species is purely space limited and spatially homogeneous. This situation can be studied for microbial colonies grown under precisely controlled conditions on petri dish with hard agar and rich growth medium. Under these conditions one expects the colony to form compact Eden-type clusters, which has recently been shown for various species including S. cerevisiae, E. coli, B. subtilis and S. marcescens.

The Eden model has been introduced as a basic model for the growth of cell colonies. It has later been shown to be in the KPZ universality class, which describes the scaling properties of a large generic class of growth models. In recent detailed studies of E. coli and S. cerevisiae quantitative evidence for the KPZ scaling of growth patterns has been identified. The models used in these studies ignored all microscopic details reproduction, such as anisotropy of cells, and could therefore not explain or predict differences observed for different species. Nevertheless, they provided a good reproduction of the basic features such as KPZ exponents, which is a clear indication that segregation itself is an emergent phenomenon. For S. cerevisiae, the domain boundaries are less rough when compared to E. coli, leading to a finer pattern consisting of a larger number of sectors. In this paper we focus on the effect of time correlations introduced by reproduction times that are not exponentially distributed (as would be in continuous time Markovian simulations), but have a unimodal distribution with smaller variation coefficient. This is very relevant in most biological applications (see e.g.) and even in spatially isotropic systems the resulting temporal correlations lead to more regular growth and therefore smaller fluctuations of the boundaries, with an effect on the patterns as seen in Fig.2.
To systematically study these temporal correlations, we introduce a generic one-parameter family of reproduction times, explained in detail in Section II. We establish that the growth clusters and competition interfaces still show the characteristic scaling within the KPZ universality class, and the effect of the variation coefficient is present only in prefactors. We predict these effects quantitatively and find good agreement with simulation data; these results are presented in Section III. More realistic reproduction time distributions with a higher number of parameters are considered in Section IV where we show that to a good approximation the effects can be summarized in the variation coefficient and mapped quantitatively onto our generic one-parameter family of reproduction times. Therefore, our results are expected to hold quite generally for unimodal reproduction time distributions, and the variation coefficient alone determines the leading order statistics of competition patterns.

II. THE MODEL

For regular reproduction times with small variation coefficient the use of a regular lattice would lead to strong lattice effects that affect the shape of the growing cluster. To avoid these we use a more realistic Eden growth model in a continuous domain in $\mathbb{R}^2$ with individuals modelled as circular hard-core particles with diameter 1, since we want to study purely the effect of time correlations. This leads to generalized Eden clusters which are compact with an interface that is rough due to the stochastic growth dynamics.

Let $B(t)$ denote the general index set of particles $p$ at time $t$, $(x_p, y_p) \in \mathbb{R}^2$ is the position of the centre of particle $p$, and $s_p \in \{1, 2\}$ is its type. We write $B(t) = B_1(t) \cup B_2(t)$ as the union of the sets of particles of type 1 and 2. We also associate with each particle the time it tries to reproduce next, $T_p > 0$. Initially, $T_p$ are i.i.d. random variables with distribution $F_3$ with parameter $\delta \in [0, 1]$, which is explained in detail below. After each reproduction $T_p$ is incremented by a new waiting time drawn from the same distribution. Note that we focus entirely on the neutral case, i.e. the reproduction time is independent of the type and both types have the same fitness. We describe the dynamics below in a recursive way.

Following a successful reproduction event of particle $p$ at time $T_p$, a new particle with index $q = |B(T_p^-)| + 1$ is added with the same type $s_q = s_p$,

$$B_{s_q}(T_p^+) = B_{s_q}(T_p^-) \cup \{q\}$$

(1)

Here $B(T^-)$ and $B(T^+)$ denote the index set just before and just after time $T$. The position of the new particle is given by

$$(x_q, y_q) = (x_p, y_p) + (\cos \phi, \sin \phi)$$

(2)

where $\phi \in [0, 2\pi)$ is drawn uniformly at random. This is subject to a hard-core exclusion condition for circular particles, i.e. the euclidean distance to all other particle centres has to be at least 1, as well as to other constraints depending on the simulated geometry as explained below. Note that in our model the daughter cell touches its mother, which is often realistic but in fact not essential, and the distance could also vary stochastically over a small range. The new reproduction times of mother and daughter are set as

$$T_p \mapsto T_p^{old} + T, \quad T_q = T_q^{old} + T',$$

(3)

where $T, T'$ are i.i.d. reproduction time intervals with distribution $F_3$. There can be variations on this where mother and daughter have different reproduction times, which are discussed in Section IV. The next reproduction event will then be attempted at $t = \min \{T_q : q \in B(T_p^+)\}$. Reproduction attempts can be unsuccessful, if
there is no available space for the offspring due to blockage by other particles. In this case the attempt is abandoned and $T_p$ is set to $\infty$, as due to the immobile nature of the model this particle will never be able to reproduce.

The initial conditions for spatial coordinates and types depend on the situation that is modelled. In this paper we mostly focus on an upward growth in a strip of length $L$ with periodic boundary conditions on the sides, where we take $B(0) = \{1, \ldots, L\}$ with $(x_p, y_p) = (p, 0)$, for all $p \in B(0)$. The initial distribution of types can be either regular or random depending on whether we study single or interacting boundaries, and will be specified later.

In Section III for our main results we use reproduction times

$$T \sim 1 - \delta + \text{Exp}(1/\delta) \ , \ \delta \in (0,1] \ ,$$

i.e. $T$ has exponential distribution with a time lag $1 - \delta \in [0,1)$ and with mean fixed to $(T) = 1$ for all $\delta$. The corresponding cumulative distribution function $F_{\delta}$ is given by

$$F_{\delta}(t) = \begin{cases} 0 & t \leq 1 - \delta \\ 1 - e^{-(t-1+\delta)/\delta} & t \geq 1 - \delta \end{cases} .$$

The variation coefficient of this distribution is given by the standard deviation divided by the mean, which turns out to be just

$$\frac{\sqrt{(T^2) - (T)^2}}{(T)} = \frac{\delta}{1} = \delta .$$

With this family we can therefore study reproduction which is more regular then exponential with a fixed average growth rate of unity (equivalent of setting the unit of time).

For $\delta = 1$ this is a standard Eden cluster, but $\delta < 1$ introduces time correlations. While the correlations affect the fluctuations, we present convincing evidence that they decay fast enough not to change the fluctuation exponents, so the system remains in the KPZ universality class. Furthermore we make quantitative predictions on the $\delta$-dependence of non-universal parameters and compare them to simulations. The more synchronized growth leads to effects similar to the ones seen in experiments (Fig. 1). To give a visual impression of the patterns produced by the model, we show in Fig. 2 two growth patterns with $\delta = 1$ and 0.1. The initial condition is a circle, and the types are distributed uniformly at random. The patterns are qualitatively similar to the experimental ones in Fig. 1 and more regular growth leads to a finer sector structure. The same effect is shown on Fig. 3 for the simulations in a linear geometry with periodic boundary conditions, which is analyzed quantitatively in the next Section. Smaller values of $\delta$ also lead to more compact growth and smaller height values reached in the same time.

In Section III for our main results we use reproduction times

$$T \sim 1 - \delta + \text{Exp}(1/\delta) \ , \ \delta \in (0,1] \ ,$$

i.e. $T$ has exponential distribution with a time lag $1 - \delta \in [0,1)$ and with mean fixed to $(T) = 1$ for all $\delta$. The corresponding cumulative distribution function $F_{\delta}$ is given by

$$F_{\delta}(t) = \begin{cases} 0 & t \leq 1 - \delta \\ 1 - e^{-(t-1+\delta)/\delta} & t \geq 1 - \delta \end{cases} .$$

The variation coefficient of this distribution is given by the standard deviation divided by the mean, which turns out to be just

$$\frac{\sqrt{(T^2) - (T)^2}}{(T)} = \frac{\delta}{1} = \delta .$$

With this family we can therefore study reproduction which is more regular then exponential with a fixed average growth rate of unity (equivalent of setting the unit of time).

For $\delta = 1$ this is a standard Eden cluster, but $\delta < 1$ introduces time correlations. While the correlations affect the fluctuations, we present convincing evidence that they decay fast enough not to change the fluctuation exponents, so the system remains in the KPZ universality class. Furthermore we make quantitative predictions on the $\delta$-dependence of non-universal parameters and compare them to simulations. The more synchronized growth leads to effects similar to the ones seen in experiments (Fig. 1). To give a visual impression of the patterns produced by the model, we show in Fig. 2 two growth patterns with $\delta = 1$ and 0.1. The initial condition is a circle, and the types are distributed uniformly at random. The patterns are qualitatively similar to the experimental ones in Fig. 1 and more regular growth leads to a finer sector structure. The same effect is shown on Fig. 3 for the simulations in a linear geometry with periodic boundary conditions, which is analyzed quantitatively in the next Section. Smaller values of $\delta$ also lead to more compact growth and smaller height values reached in the same time.

III. MAIN RESULTS

A. Quantitative analysis of the colony surface

In this Section we provide a detailed quantitative analysis of the $\delta$ family of models in linear geometry with periodic boundary conditions (see Fig. 3), starting with the dynamical scaling properties of the growth interface.

We regularize the surface to be able to define it as a function of the lateral coordinate $x$ and time $t$ as

$$y(x, t) := \max \{y_p : p \in B(t), |x_p - x| \leq 1\} .$$

In case of overhangs (which are very rare) we take the largest possible height, and due to the discrete nature of our model this leads to a piecewise constant function.

The surface of a standard Eden growth cluster is known to be in the KPZ universality class \[16, 18\], i.e. a suitable scaling limit of $y(x, t)$ with vanishing particle diameter fulfills the KPZ equation

$$\partial_t y(x, t) = v_0 + \nu \Delta y(x, t) + \frac{\lambda}{2} (\nabla y(x, t))^2 + \sqrt{D} \eta(x, t) .$$

Here $v_0$, of the order of unity, corresponds to the growth rate of the initial flat surface (related to the mean reproduction rate and some geometrical effects), the surface tension term with $\nu > 0$ represents surface relaxation, and the nonlinear term represents the lowest order contribution to lateral growth \[18\]. The fluctuations due to stochastic growth are described by space-time white noise $\eta(x, t)$, which is a mean 0 Gaussian process with correlations

$$\langle \eta(x, t) \eta(x', t') \rangle = \delta(x-x')\delta(t-t') .$$

We denote the average surface height by

$$h(t) := \frac{1}{L} \int_0^L y(x, t) \, dx ,$$

which is a monotone increasing function in $t$. It is also asymptotically linear and therefore we will later also use...
of two system sizes, and for a number of different values $z$ and the dynamic exponent is
exponent is

versality classes such as Edward Wilkinson. For the KPZ

Such a scaling behaviour has been shown for many dis-

The roughness of the surface is given by the root mean

squared displacement of the surface height as a function

of time. The $\delta$-dependence of the average

growth velocity of height as seen in Fig. 3 does not lead
to leading order contributions to the statistical properties

of the surface or the structure of sectoring patterns.

The main properties of the surface $y(x,t)$ can then be

characterized by the Family-Vicsek scaling relation of the

roughness

$$S(t) = L^\alpha f(t/L^2) ,$$  \hspace{1cm} (12)

where the scaling function $f(u)$ has the property

$$f(u) \propto \begin{cases} u^\beta & u \ll 1 \\ 1 & u \gg 1 \end{cases} .$$  \hspace{1cm} (13)

Such a scaling behaviour has been shown for many dis-
crete models including ballistic deposition and continuum

growth \cite{3, 10, 18, 26, 27}, and holds also for other uni-

versality classes such as Edward Wilkinson. For the KPZ
class in 1+1 dimensions the saturated interface roughness

exponent is $\alpha = 1/2$, the growth exponent is $\beta = 1/3$,
and the dynamic exponent is $z = \alpha/\beta = 3/2$.

Fig. 4 shows a data collapse for the roughness $S(t)$ for
two system sizes, and for a number of different values of $\delta$.
As $\delta$ gets smaller, the surface becomes less rough
due to a more synchronized growth. The dashed lines
indicate the power law growth with exponent $\beta = 1/3$ in
the scaling window. This window ends around $t/L^2 \approx 1$
due to finite size effects, where the lateral correlation
length reaches the system size and the surface fluctuations
saturate. For small $t$ the system exhibits a transient
behaviour before entering the KPZ scaling due to local
correlations resulting from the non-zero particle size and
stochastic growth rules. As we quantify later, these
correlations are much higher for more synchronized growth
at small $\delta$, which leads to a significant increase in the
transient regime. The transient time scale is independent
of system size and vanishes in the scaling limit, so that
the length of the KPZ scaling window increases with
$L$. This behaviour can be observed in Fig. 4 where for
the smallest value $\delta = 0.2$ the scaling regime is still hard
to identify for the accessible system sizes.

Another characteristic quantity is the height-height
correlation function defined as $C(l, t)$ \cite{3, 28, 29}

$$C(l, t) = \left( \frac{1}{L} \int_0^L (y(x, t) - y(x+l, t))^2 dx \right)^{1/2} .$$ \hspace{1cm} (14)

For a KPZ surface in 1+1 dimensions this obeys the
scaling behaviour

$$C(l, t) \sim \begin{cases} \left( \frac{D}{\nu} \right)^{1/2} l \ll \xi_\parallel(t) \\ \left( \frac{D}{\nu} \right)^{2/3} (\lambda t)^{1/3} l \gg \xi_\parallel(t) \end{cases} ,$$ \hspace{1cm} (15)

where $\xi_\parallel(t)$ is defined to be the lateral correlation length
scale and takes the form $\xi_\parallel \sim (D/2\nu)^{1/3} (\lambda t)^{2/3}$.

A detailed computation can be found in Appendix B.
comes comparable to one particle diameter, var(\delta_i) the time correlation induces a fixed intrinsic parameters of (8). This is shown in Fig. 5, where C_i into the power law in Fig. 5, using that the proportionality constant is very close to 1 (cf. derivation (B11) in the Appendix). The data are in good agreement with the prediction with fitted parameters \epsilon \approx 0.42 and D/(2\nu)(\delta = 1) \approx 1.1.

with l, and when l exceeds the lateral correlation length \xi_i(t) it reaches a value that depends on the time t and the parameters of (8). This is shown in Fig. 5, where C_i(t, t) is plotted for various values of \delta, and the data agree well with the exponent \alpha = 1/2 for the KPZ class indicated by dashed lines.

The time correlations introduced by the partial synchronization can be estimated by considering a chain of N growth events where each particle is the direct descendent of the previous one. Each added particle corresponds to a height change \Delta y_i, and has an associated waiting time T_i with distribution \[p\]_. During time t there are N(t) growth events, and since the average reproduction time is 1 with variance \delta^2, we have \langle N(t) \rangle \approx t\delta^2t. The height of the last particle is \[y_{N(t)} = \sum_i N(t) \Delta y_i,\] leading to

\[\text{var}(y_{N(t)}) = \langle \Delta y_i \rangle^2 \text{var}(N(t)) + \langle N(t) \rangle \text{var}(\Delta y_i). \tag{17}\]

The terms in this expression correspond to two sources of uncertainty: (i) due to the randomness in T_i the number of growth events vary with var(N(t)), and (ii) the individual height increments are random with var(\Delta y_i). This leads to

\[\text{var}(y_{N(t)}) \approx t \langle \Delta y_i \rangle^2 (\delta^2 + \epsilon^2), \tag{18}\]

where \epsilon = \sqrt{\text{var}(\Delta y_i)/\langle \Delta y_i \rangle}\) denotes the variation coefficient of the height fluctuations due to geometric effects.

We define the correlation time \tau as the amount of time by which the uncertainty of the height of the chain becomes comparable to one particle diameter, var(y_{N(t)}(\tau)) = O(1). Since \langle \Delta y_i \rangle is largely independent of \delta (cf. Appendix A), the time correlation induces a fixed intrinsic vertical correlation length

\[\tau \sim \frac{1}{\delta^2 + \epsilon^2} \tag{19}\]

in the model. This correlation length reduces fluctuations and leads to an increase in the saturation time \[t_{sat}\] of the system, namely \[t_{sat}/\tau \sim L^2,\] a modification of the usual relation with the system size L. Analogous to the standard deviation of the time-dependence of the lateral correlation length [3], this leads to

\[\xi_l(t) \sim (t/\tau)^{1/2}. \tag{20}\]

Together with (10) from the behaviour of the correlation length, we expect

\[D/(2\nu) \sim (\delta^2 + \epsilon^2)^2, \tag{21}\]

since \lambda turns out to be largely independent of \delta. This is shown to be very good agreement with the data in Fig. 6 for fitted values of \epsilon and a prefactor. The fit value for \epsilon and the ratio D/(2\nu) for \delta = 1 (the usual Eden model) are compatible with simple theoretical arguments (see Appendix A). So the very basic argument above to derive an intrinsic vertical correlation length explains the \delta-dependence of the surface properties very well. Measuring height in this intrinsic length scale, we observe a standard KPZ behaviour with critical exponents being unchanged, since the intrinsic correlations are short range (i.e. decay exponentially on the scale \tau). This is in contrast to effects of long-range correlations where the exponents typically change, see e.g. studies with long-range temporally correlated noise [11, 53] or memory and delay effects using fractional time derivatives and integral/delay equations [34, 36].

B. Domain boundaries

In this section we derive the superdiffusive behaviour of the domain boundaries between the species from the scaling properties of the interface. Since the boundaries grow locally perpendicular to the rough surface, they are expected to be superdiffusive with Hurst exponent 2/3, which has been shown for a solid on solid growth model in [37] and has been observed in [15] for experimental data. In order to confirm this quantitatively for our model, we perform simulations with initial conditions \[X_1(0) = \{1, \ldots, \lfloor L/2 \rfloor\} \text{ and } X_2(0) = \{\lceil L/2 \rceil + 1, \ldots, L\},\] i.e. the initial types are all red on the left half and all green on the right half of the linear system. Therefore we have two sector boundaries \[X_1\] and \[X_2\] with initial positions \[X_1(0) = 1/2 \text{ and } X_2(0) = \lfloor L/2 \rfloor + 1/2.\] After growing the whole cluster, we define the boundary as a function of height via the leftmost particle in a strip of width 2 and medium height \[h:\]

\[X_1(h) = \min \{x_p + 1/2 : |y_p - h| < 1, p \in B_1\}\]
\[X_2(h) = \min \{x_p + 1/2 : |y_p - h| < 1, p \in B_2\}, \tag{22}\]
follows a power law with exponent 4. Each curve for the collapse in (a) follows the prediction (24). The system size is \( L = 1000 \) and the data is averaged over 500 samples and the error bars are comparable to the size of the symbols. (a) Data collapse of the normalized quantity \( M(h)/\sigma^2 \) as a function of height \( h \) for several values of \( \delta \). The values in the normalization \( \sigma^2 \) are taken from the best fit shown as full line in (b). Each curve follows a power law with exponent 4/3, the line corresponding to \( h^{4/3} \) is shown as comparison. (b) The prefactor \( \sigma^2 \), where the data are best fits according to (24). The full line used for the collapse in (a) follows the prediction \((\delta^2 + \epsilon^2)^{4/3}\) with fitted \( \epsilon = 0.40 \), which is compatible with the fit in Fig. 0.

where we take the periodic boundary conditions into account. The simulations are performed on a system of size \( L = 1000 \), and run until a time of \( t = 2000 \), which is well before the expected time of annihilation, which is of order \( L^{3/2} \) proportional to the saturation timescale in the KPZ class. Therefore we can treat the sector boundaries as two independent realizations of the boundary process \((X(h) : h \geq 0)\).

As has been noted already in [37], this process is expected to follow the same scaling as the lateral correlation length. For the mean square displacement

\[
M(h) := \left\langle (X(h) - X(0))^2 \right\rangle
\]

we therefore get with (16) and (21), using the linear relationship between \( h \) and \( t \),

\[
M(h) \approx \sigma^2 h^{4/3} \sim \varepsilon^2(h)
\]

where \( \sigma^2 \propto (\delta^2 + \epsilon^2)^{4/3} \). This prediction is in very good agreement with data for the scaling of \( M(h) \) and its prefactor as presented in Fig. 7 and the fit value for \( \epsilon^2 \) is consistent with the one in Fig. 6. As before, for \( D/(2\nu) \) the \( \delta \)-dependence is absorbed by the prefactor, and the power law exponent 4/3 for \( M(h) \) remains unchanged from standard KPZ behaviour studied also in [37].

We can further investigate the law of the process \((X(h) : h \geq 0)\). The data presented in Fig. 8(a) clearly support that \( X(h) \) is a Gaussian process. A fractional Brownian motion with stationary increments seems to be a natural model for the \( X(h) \) in the KPZ scaling window. This is confirmed by the behaviour of the correlation function \( \langle X(h + \Delta h)X(h) \rangle \), which is shown in Fig. 8(b) for various \( \delta \) and two values of the lag \( \Delta h > 0 \). For a fractional Brownian motion with mean square displacement (24) we expect

\[
\langle X(h+\Delta h)X(h) \rangle \approx \frac{\sigma^2}{2} (h+\Delta h)^{4/3} + h^{4/3} - |\Delta h|^{4/3}
\]

for all \( \Delta h > 0 \) and \( h > 0 \) sufficiently large to have no effects from the flat initial condition. For simplicity we have assumed here that \( X(0) = 0 \).

This is in good agreement with the data, and we conclude that the sector boundaries can be modeled by fractional Brownian motions with superdiffusive Hurst exponent 2/3 and a \( \delta \)-dependent prefactor \( \sigma_\delta \) (24).

C. Sector patterns

In [19], and also [20, 22] under the assumption of diffusive scaling, it was shown how the understanding of the single boundary dynamics leads to a prediction for sector statistics for well-mixed initial conditions. In this section we shortly review this approach and show that it carries over straightforward to systems with \( \delta < 1 \). The sector boundaries \( X_i(h) \) interact by diffusion limited annihilation which drives a coarsening process, as can be seen in Fig. 8 for two linear populations with different values of \( \delta \). Both systems have the same initial condition with a flat line of particles of independently chosen types, and the finer coarsening patterns for smaller values of \( \delta \) result from the reduced boundary fluctuations due to the prefactor \( \sigma_\delta \) (24).

Let \( N(h) \) be the number of sector boundaries at height \( h \geq 0 \) as defined in [23]. For systems of diffusion limited annihilation [23, 51] it is known that \( N(h) \) is inversely
proportional to the root mean square displacement, and decays according to

$$\langle N(h) \rangle \approx \frac{1}{\sqrt{4\pi M(h)}} \sim \frac{1}{\sigma_8} h^{-2/3}.$$  \hfill (26)

This prediction is confirmed in Fig. 9 where we plot $$\langle N(h) \rangle$$ for various $$\delta$$, and obtain a data collapse by multiplying the data with $$\sqrt{4\pi \sigma_8^2 / L}$$, as shown in Figure 3. For $$\delta = 1$$, the final height is $$h \approx 70$$ leading to $$\langle N(h) \rangle \approx 7.6$$, and for $$\delta = 0.1$$, $$h \approx 40$$ with $$\langle N(h) \rangle \approx 32$$. These numbers are compatible with the simulation samples shown which have 6 and 34 sector boundaries remaining, respectively.

In general, diffusion limited annihilation is very well understood, and there are exact formulas also for higher order correlation functions [40], which can be derived from the behaviour of a single boundary [24]. This demonstrates that the behaviour of populations is fundamentally the same for all values of $$\delta$$ and characterized by the KPZ universality class, and the observed difference in coarsening patterns can be explained by the functional behaviour of the prefactors.

FIG. 8: (Color online) The sector boundary $$X(h)$$ behaves like a fractional Brownian motion. (a) The standardized probability density function (pdf) of $$X(h)$$ as a function of the rescaled argument $$x/(\sigma_x h^{2/3})$$ for different heights $$h$$ and values of $$\delta$$. The black solid parabola is the pdf of a standard Gaussian on a logarithmic scale. (b) The covariance function $$\langle X(h + \Delta h)X(h) \rangle$$ shows the behaviour (24), which is plotted as the solid black curve. After rescaling we get a data collapse as a function of $$h/\Delta h$$, which agrees well with the prediction if $$h$$ is sufficiently large and the flat boundary conditions become irrelevant. Data are averages over 1000 realizations and the error bars are comparable to the size of the symbols.

Using [26], we can predict the expected number of sector boundaries at the final height in the simulations shown in Figure 8. For $$\delta = 1$$, the final height is $$h \approx 70$$ leading to $$\langle N(h) \rangle \approx 7.6$$, and for $$\delta = 0.1$$, $$h \approx 40$$ with $$\langle N(h) \rangle \approx 32$$. These numbers are compatible with the simulation samples shown which have 6 and 34 sector boundaries remaining, respectively.

IV. REALISTIC REPRODUCTION TIMES

In this section we study the effect of more realistic reproduction time distributions on the sectoring patterns, and how they can be effectively described by the previous $$\delta$$-dependent family of distributions. In particular, we focus on S. cerevisiae, which is one of the species included in [13], and for which reproduction time statistics is available [23, 25] by the use of time lapsed microscopy. S. cerevisiae cells have largely isotropic shape so that spatial correlations during growth should be minimal, fitting the assumptions of our previous model. However, when cells divide the cells the mother cell forms a bud on its surface which separates from the mother after growth to become a daughter cell. The mother can then im-
in (24) and Fig. 7. The data correspond to reproduction times with the δ-family of realistic reproduction times of mother cells $T_r$ (full red line) and daughter cells $T_m + T_r$ (dashed red line) with normalized mean compared to $T$ from (24) with corresponding δ (blue). (b) The prefactor of the mean squared displacement $\sigma^2_T$ as introduced in (23) and Fig. 7. The data correspond to reproduction times $T_r$ for all cells (denoted M), $T_m + T_r$ for all cells (denoted D) and the most realistic mixed model (denoted M and D) as explained in the text. All these cases are consistent with previous results from Fig. 7.

immediately restart this reproduction process, whereas the daughter cell has to grow to a certain size in order to be classed as a mother and to be able to reproduce. We denote this time to maturity by $T_m$ and the reproduction time of (mother) cells by $T_r$.

The results in [23,24] suggest that Gamma distributions are a reasonable fit for the statistics for $T_m$ and $T_r$, where

$$T_r \sim \rho_0 + \text{Gamma}(\rho_1, \rho_2),$$  \hspace{1cm} \text{(27)}

with delay $\rho_0 > 0$. The parameters $\rho_1, \rho_2$ denote the shape and scale of the Gamma distribution, which has a probability density function

$$f_{\rho_1,\rho_2}(t) = \rho_1^{-1} \exp\left(-\frac{t}{\rho_2}\right) \Gamma(\rho_1) \rho_2^{\rho_1}, \quad t \geq 0.$$  \hspace{1cm} \text{(28)}

The time to maturity is distributed as

$$T_m \sim \text{Gamma}(\rho_3, \rho_4),$$  \hspace{1cm} \text{(29)}

and in [25] data are presented for which the parameters can be fitted to $\rho_0 \approx 1.0$, $\rho_1 \approx 1.7$, $\rho_2 \approx 0.51$, $\rho_3 \approx 9$ and $\rho_4 \approx 0.3$. The unit of $\rho_0, \rho_2$ and $\rho_4$ are hours and $\rho_1, \rho_3$ are dimensionless numbers.

The random variables $T_m$ and $T_r$ may be assumed to be independent and the time until a newly born daughter cell can reproduce is distributed as the sum $T_m + T_r$. Note that the expected value of reproduction times $(T_r) = \rho_0 + \rho_1 \rho_2 = 1.86$ is smaller than that for times to maturity $(T_m) = \rho_3 \rho_4 = 2.52$ but of the same order. The real time scale for these numbers is hours, but we are only interested in the shape of these distributions rescaled to mean 1 like our previous model.

The distribution of $\delta$-dependent reproduction times can be written as $T \sim 1 - \delta + \text{Gamma}(1, \delta)$, since exponentials are a particular case of Gamma random variables with shape parameter 1. The reproduction time $T_r$ of mother and $T_m + T_r$ of daughter cells are also unimodal with a delay, and very similar in shape to $T$ in our model. This can be seen in Fig. 10(a), where we plot the probability densities renormalized to mean 1. Analogous to [20], we can compute the variation coefficients of $T_r$ and $(T_m + T_r)$, which turn out to be 0.356 and 0.244, respectively. To confirm that the behaviour of sector boundaries can be well predicted by the variation coefficient, we present data of three simulations in Fig. 10(b): one with reproduction times $T_r$ for mother and $T_d + T_r$ for daughter cells as explained above, one with $T_r$ for all cells, and one with $T_r + T_m$ for all cells. The mean squared displacement $M(t)$ for these models also shows a power law with exponent 4/3 analogous to Fig. 7 and the prefactors $\sigma^2_T$ match well with our simplified model.

To estimate the variation coefficient in the model with mother and daughter cells, we measure the fraction of reproduction events of daughter cells to be $p_d = 0.88$, and $p_m = 0.12$ for mother cells. The reproduction time of the union of mother and daughter cells is then taken as

$$T = \Theta(T_m + T_r) + (1 - \Theta)T_r,$$  \hspace{1cm} \text{(29)}

where the independent Bernoulli variable $\Theta \sim \text{Be}(p_d) \in \{0, 1\}$ indicates reproduction of a daughter. The variation coefficient of $T$ turns out to be 0.322. In all three combinations of realistic reproduction times we find that the generic family of $F_3$ introduced in [24] provides a good approximation for the properties of domain boundaries in simulations. We expect this to hold for a large class of microbial species which have similar reproduction times with unimodal structure and do not exhibit significant spatial correlations due to shape.
We have introduced a generic generalization of the Eden growth model with competing species, regarding the reproduction time statistics of the individuals. This is highly relevant in biological growth phenomena, and can have significant influence on the sectoring patterns observed e.g. in microbial colonies. Although microbial species growth is the prime example, our results also apply to more general phenomena of space limited growth with inheritance, where the entities have a complex internal structure that leads to non-exponential reproduction times, such as colonization/range expansions or epidemic spreading of different virus strands. Our main result is that, as long as the reproduction time statistics have finite variation coefficients, the induced sectoring patterns are local and the macroscopic behaviour of the system is well described by the KPZ universality class. The dependence of the relevant parameters in that macroscopic description on the variation coefficient (a microscopic property of the system) is well understood by simple heuristic arguments, which we support with detailed numerical evidence.

The results in this paper can be used for quantitative predictions of sectoring patterns for species of approximately isotropic shape, such as S. cerevisiae. It is an interesting question if the simple mechanism of time correlations due to reproduction time statistics with variable variation coefficients is enough to quantitatively explain sectoring patterns in real experiments, which is currently under investigation. It could well be that other factors influencing e.g. the choice of growth direction have to be included, to account for an effective attraction of cells which is often observed in the growth of microbial colonies. Such an effect would further smoothen the surface and the fluctuations of sector boundaries. In this paper we have focused on purely temporal correlations, but it should also be possible to describe spatial effects due non-isotropic particle shapes with the same methods.

Appendix A: Effect of geometric disorder

The squared variation coefficient $\epsilon^2$ in [19] due to geometric disorder has been consistently fitted to values around 0.4 with our data in Section [11]. This value is compatible with the following very simple argument. Consider a single growth event around an isolated spherical particle with diameter 1, with direction $\alpha$ chosen uniformly in a cone with opening angle $\pi/2$ around the vertical axis. This leads to

$$\langle \Delta y_i \rangle = \int_{-\pi/2}^{\pi/2} \cos \alpha \, d\alpha = 0.64$$

and

$$\epsilon^2 \approx \left( \int_{-\pi/2}^{\pi/2} \cos^2 \alpha \, d\alpha - \langle \Delta y_i \rangle^2 \right) / \langle \Delta y_i \rangle^2 \approx 0.23 , \quad (A1)$$

which is of the same order as the fitted values. Choosing only a slightly larger opening angle $0.55\pi$ of the cone leads to $\epsilon^2 \approx 0.39$ and $\langle \Delta y_i \rangle \approx 0.57$. These are in good agreement with the fitted values and with measurements of $\langle \Delta y_i \rangle$ (not shown). The latter show some dependence on $\delta$, related also to the compactness of growth as seen in Figs. [2] and [3] but this does not contribute to our results on a significant level so we ignore this dependence. Actual growth events in the simulation are of course often obstructed by neighbouring particles, but the right order of magnitude of the parameters can be explained by the basic argument above.

Appendix B: Deriving the correlation function $C(l, t)$

We use the mode coupling method [29], in order to find an exact analytical expression of the correlation function Eq. (14) as shown in Eq. (15). The idea of the mode coupling approximation is that properties of solutions of the KPZ equation [3] may be derived by first considering the linear Edwards-Wilkinson equation [41] for $\lambda = 0$. We further consider the co-moving frame, so that $v_0 = 0$, and the equation then reads

$$\partial_t y(x, t) = \nu \Delta y(x, t) + \sqrt{D} \eta(x, t). \quad (B1)$$

We denote by

$$\hat{y}(k, t) = \int_{-\infty}^{\infty} dx \, y(x, t) e^{-ikx}$$

the Fourier transform of the function $y(x, t)$. The evolution of the function $\hat{y}(k, t)$ satisfies

$$\partial_t \hat{y}(k, t) = -\nu k^2 \hat{y}(k, t) + \sqrt{D} \hat{\eta}(k, t). \quad (B2)$$

Here $\hat{\eta}(k, t)$ is the spatial Fourier transform of the white noise $\eta(x, t)$, where $\hat{\eta}(k, t)$ has a mean 0 with correlations

$$\langle \hat{\eta}(k, t) \hat{\eta}(k', t') \rangle = \frac{1}{2\pi} \delta(k + k') \delta(t - t'). \quad (B3)$$

A formal solution of (B2) can be obtained, and after inverse Fourier transform this leads to

$$y(x, t) = \sqrt{D} \int_{-\infty}^{\infty} dk \, e^{ikx} \int_0^t ds \, \hat{\eta}(k, s) e^{-\nu k^2 (t-s)}. \quad (B4)$$

The correlation function $C(l, t)$ defined in (14) can be represented as

$$C(l, t)^2 = 2 \int_0^L dx \langle y(x, t)^2 - y(l+x, t) y(x, t) \rangle . \quad (B5)$$
Using the solution (B4) we can compute
\[ \int_0^L dx \langle y(l+x, t) y(x, t) \rangle = \frac{D}{2\nu \pi} \int_0^\infty dk \frac{k}{k} \left[ 1 - e^{-2\nu k^2 t} \right], \] 
(B6)
where we have used that the Fourier transform is even in \( k \). Taken together, this leads to an expression for the correlation function (13) of the Edwards-Wilkinson equation
\[ C(l, t)^2 = \frac{D}{\nu \pi} \int_0^\infty dk k^{-2} \left( 1 - \cos(kl) \right) \left[ 1 - e^{-2\nu k^2 t} \right]. \] 
(B7)

In order to compute the correlation function for the KPZ equation (5) we substitute length scale dependent parameters \( D(k) \) and \( \nu(k) \) into (B7), which are obtained from the renormalization group flow equations (18, 29). In \( d = 2 \) dimensions these are given by
\[ \nu(k) = \nu_1 (1 - \alpha_B) + \alpha_B/k^{1/2}, \]
\[ D(k) = D_1 (1 - \alpha_B) + \alpha_B/k^{1/2}, \] 
and \( \lambda(k) = \lambda_1, \) where
\[ \alpha_B = \frac{\lambda_1^2 D_1}{4\pi^2 \nu_1}. \]

Here \( (\lambda_1, \nu_1, D_1) \) are the parameters for \( k = 1 \) where no renormalization has taken place. Plugging this into (B7) and only considering the most dominant terms, we obtain
\[ C(l, t)^2 = \frac{D_1}{\nu_1 \pi} \int_0^\infty dk k^{-2} \left( 1 - \cos(kl) \right) \left[ 1 - e^{-Bk^{-3/2} t} \right], \] 
(B9)

where \( B = 2\nu_1 \alpha_B^{3/2} = \frac{\nu_1^2}{4\pi} \lambda \sqrt{D_1/2\nu_1}. \) If we take \( t \to \infty \) in Eq. (B9) we get
\[ C(l, t)^2 \to \frac{D_1}{\nu_1 \pi} \int_0^\infty dk k^{-2} \left( 1 - \cos(kl) \right) = \frac{D_1}{2\nu_1} l. \] 
(B10)

With (B11) \( D/\nu = D_1/\nu_1 \) is independent of the scale \( k \), and thus
\[ C(l, t) \approx \left( \frac{D}{2\nu} l \right)^{1/2} \quad \text{for} \quad l \ll \xi(l). \] 
(B11)

For finite time, numerical integration of (B9) in the large \( l \) limit gives
\[ \lim_{l \to \infty} C(l, t)^2 \approx 2.7 \frac{D}{2\nu} (Bt)^{2/3}. \]

Together with (B11) and the definition (14) of the correlation length this leads to
\[ \lim_{l \to \infty} C(l, t) \approx \left( 5.4 \times 2^{1/3} \left( \frac{D}{2\nu} \right)^{4/3} \pi^{-5/3} (\lambda t)^{2/3} \right)^{1/2}, \] 
(B12)

and
\[ \xi(l) \approx 5.4 \times 2^{1/3} \left( \frac{D}{2\nu} \right)^{1/3} \pi^{-5/3} (\lambda l)^{2/3}. \] 
(B13)
