ABSTRACT

Background

Selenium is a key component of a number of selenoproteins which protect against oxidative stress and have the potential to prevent chronic diseases including cardiovascular disease (CVD). However, observational studies have shown inconsistent associations between selenium intake and CVD risk; in addition, there is concern around a possible increased risk of type 2 diabetes with high selenium exposure.

Objectives

To determine the effectiveness of selenium only supplementation for the primary prevention of CVD and examine the potential adverse effect of type 2 diabetes.

Search methods

The following electronic databases were searched: the Cochrane Central Register of Controlled Trials (CENTRAL) (Issue 10 of 12, October 2012) on The Cochrane Library; MEDLINE (Ovid) (1946 to week 2 October 2012); EMBASE Classic + EMBASE (Ovid) (1947 to 2012 Week 42); CINAHL (EBSCO) (to 24 October 2012); ISI Web of Science (1970 to 24 October 2012); PsycINFO (Ovid) (1806 to week 3 October 2012); Database of Abstracts of Reviews of Effects (DARE), Health Technology Assessment Database and Health Economics Evaluations Database (Issue 4 of 4, October 2012) on The Cochrane Library. Trial registers and reference lists of reviews and articles were searched and experts in the field were approached. No language restrictions were applied.

Selection criteria

Randomised controlled trials on the effects of selenium only supplementation on major CVD end-points, mortality, changes in CVD risk factors, and type 2 diabetes were included both in adults of all ages from the general population and in those at high risk of CVD. Trials were only considered where the comparison group was placebo or no intervention. Only studies with at least three months follow-up were included in the meta-analyses, shorter term studies were dealt with descriptively.

Data collection and analysis

Two review authors independently assessed trial quality and extracted data. Study authors were contacted for additional information.
Main results

Twelve trials (seven with duration of at least three months) met the inclusion criteria, with 19,715 participants randomised. The two largest trials that were conducted in the USA (SELECT and NPC) reported clinical events. There were no statistically significant effects of selenium supplementation on all cause mortality (RR 0.97, 95% CI 0.88 to 1.08), CVD mortality (RR 0.97, 95% CI 0.79 to 1.2), non-fatal CVD events (RR 0.96, 95% CI 0.89 to 1.04) or all CVD events (fatal and non-fatal) (RR 1.03, 95% CI 0.95 to 1.11). There was a small increased risk of type 2 diabetes with selenium supplementation but this did not reach statistical significance (RR 1.06, 95% CI 0.97 to 1.15). Other adverse effects that increased with selenium supplementation, as reported in the SELECT trial, included alopecia (RR 1.28, 95% CI 1.01 to 1.62) and dermatitis grade 1 to 2 (RR 1.17, 95% CI 1.0 to 1.35). Selenium supplementation reduced total cholesterol but this did not reach statistical significance (WMD -0.11 mmol/L, 95% CI -0.3 to 0.07). Mean high density lipoprotein (HDL) levels were unchanged. There was a statistically significant reduction in non-HDL cholesterol (WMD -0.2 mmol/L, 95% CI -0.41 to 0.00) in one trial of varying selenium dosage. None of the longer term trials examined effects on blood pressure. Overall, the included studies were regarded as at low risk of bias.

Authors’ conclusions

The limited trial evidence that is available to date does not support the use of selenium supplements in the primary prevention of CVD.

PLAIN LANGUAGE SUMMARY

Selenium supplements for the prevention of cardiovascular disease

Use of selenium enriched foods, supplements and fertilizers has increased in recent years in many countries because of the perception that selenium may reduce the risk of cardiovascular disease and other chronic conditions. Therefore, it is important to understand the effects of a nutrient that is frequently supplemented on common conditions such as cardiovascular disease or diabetes. This review assessed the effects of providing selenium supplements to healthy adults in order to prevent the occurrence of cardiovascular disease. Whether selenium supplements would reduce the risk factors associated with heart disease was also examined. We found 12 trials in which 19,715 healthy adults were randomly assigned to receive selenium supplements or placebo. The vast majority of participants involved in these trials were male individuals from the US, where people are already well nourished and take large amounts of selenium from natural foods. Overall, the included studies were regarded as at low risk of bias. In our review, providing selenium supplements to healthy adults did not prevent the occurrence of major cardiovascular disease. The increased risk of developing type 2 diabetes when taking selenium supplements, as suggested in some previous studies, could not definitely be ruled out in our review. In summary, this review of the available evidence to date suggests that taking selenium supplements is neither beneficial nor harmful for cardiovascular disease, but it is probably unnecessary for those who are already well nourished and who take large amounts of selenium from natural foods.

BACKGROUND

Description of the condition

Cardiovascular disease (CVD) is still the number one cause of death and disability worldwide (WHO 2011). In 2008 it accounted for 30% of total global deaths, with 6.2 million deaths the consequence of stroke and 7.2 million due to coronary heart disease (CHD) (WHO 2011). The burden of disease will increase with an aging population and increasing levels of obesity and sedentary lifestyles. Prevention of CVD by targeting modifiable factors remains a key public health priority. Diet plays a major role in the aetiology of many chronic diseases, including CVD, thereby contributing to a significant geographical variability in morbidity and mortality rates across different countries and populations worldwide (WHO 2003).

Description of the intervention

Selenium is a trace element that is essential to humans, and is currently the focus of major scientific debate and investigation...
Selenium supplementation for the primary prevention of cardiovascular disease (Review)

Copyright © 2013 The Cochrane Collaboration. Published by John Wiley & Sons, Ltd.

A recent Cochrane systematic review (Dennert 2011) examining the effect of selenium in the prevention of cancer found from observational studies that people with higher selenium levels or intake had a lower frequency of certain cancers (such as bladder or prostate cancer) but results from trials of selenium supplementation were inconsistent. For CVD, a number of observational studies have examined the association between selenium status and risk of CHD and other CVD end-points across different populations (Bleys 2008; Bleys 2009; Flores-Mateo 2006; Salonen 1982; Virtamo 1985; Wei 2004). Although some of the early studies suggest possible inverse associations, especially in populations with relatively low dietary selenium intakes (Flores-Mateo 2006; Salonen 1982; Virtamo 1985; Wei 2004), more recent observational evidence is suggestive of a possible U-shaped association between selenium status and CVD risk, at least in selenium-replete populations such as in the United States (US) (Bleys 2008; Bleys 2009).

Results from randomised controlled trials of selenium supplementation do not, however, provide conclusive evidence to support a role for selenium in CVD disease prevention (Brown 2001; Flores-Mateo 2006; Herberg 2004; Korpela 1989; Kuklinski 1994; Stranges 2006; You 2001). In a post hoc analysis from the Nutritional Prevention of Cancer (NPC) trial in the US (Stranges 2006), selenium supplementation alone (200 µg/day as high-selenium yeast) was not significantly associated with any of the CVD end-points after 7.6 years of follow-up. Other randomised controlled trials that have examined the effect of selenium in combination with other vitamins or minerals on CVD end-points have also yielded inconclusive findings (Brown 2001; Herberg 2004; Korpela 1989; Kuklinski 1994; You 2001).

The intervention to be examined in the current review is selenium supplementation as a single ingredient. Selenium is a key component of a number of selenoproteins involved in essential enzymatic functions such as redox homeostasis, thyroid hormone metabolism, immunity and reproduction (Burk 2002; Papp 2007). There is a longstanding recognition that selenium deficiency, as originally observed in North-eastern provinces of China in the 1970s, is associated with the occurrence of diseases such as cardiomyopathy (Keshan disease) and athropathy (Kashim-Beck disease), with potential reversal of these conditions with selenium supplementation (Keshan Disease Research Group; Rayman 2000). In addition, because of the potential of these selenoproteins to protect against oxidative stress, significant expectations have been raised for a role for selenium in the prevention of several chronic diseases commonly associated with oxidative stress including cancer, CVD and type 2 diabetes (Combs 1998; Neve 1996; Rayman 2000).

However, there is some evidence of potential adverse effects of selenium supplementation. Recent findings from observational studies and randomised controlled trials have raised concerns that high selenium exposure may lead to adverse cardio-metabolic effects, at least in selenium-replete populations, such as an increased risk of diabetes, hypertension and hyperlipidemia (LaClaustra 2009a; Stranges 2007; Stranges 2010b). For example, in a post hoc analysis of the NPC trial in the Eastern US (Stranges 2007), supplementation with selenium alone (200 µg/day as high-selenium yeast) increased the risk of type 2 diabetes compared to placebo, particularly in men and in participants with high baseline plasma selenium (hazard ratio of 2.70 in the highest tertile of plasma selenium, that is > 121.6 ng/ml). In addition, the recent Cochrane review examining the effect of selenium for the prevention of cancer also highlighted the potential adverse effects of selenium supplementation notably gastrointestinal upset, alopecia and an increased risk of type 2 diabetes (Dennert 2011).

How the intervention might work

In theory, potential CVD benefits of selenium supplements are supported by the ability of selenoproteins such as glutathione peroxidase (GPxs) and selenoprotein S to combat the oxidative modification of lipids, inhibit platelet aggregation and reduce inflammation (Blankenberg 2003; Brigelius-Flohe 2003; Curran 2005; Gao 2006; Neve 1996; Salonen 1988; Sattler 1994; Vuhta 2007). However, selenium has a narrow therapeutic window and there is considerable individual variability in terms of metabolic sensitivity and optimal selenium intake (Whanger 1996). Part of the inconsistencies in the effect of selenium supplements on cardio-metabolic outcomes in different studies might be explained by the variability of selenium status and selenium intake across countries and population subgroups (Rayman 2009; Stranges 2010a). In this view, the association between selenium and cardio-metabolic outcomes is likely to be U-shaped, with potential harm occurring at selenium levels both below and above the physiological range for optimal activity of selenoproteins. For example, recent findings from the UK PRECISE Pilot trial among 501 elderly volunteers with a relatively low selenium status showed that supplementation with selenium alone at 100 and 200 µg/day significantly decreased total and non-HDL cholesterol concentrations, and that the ratio of total-to-HDL cholesterol decreased progressively with increasing selenium doses (Rayman 2011).

Why it is important to do this review

Selenium deficiency, as observed in North-eastern provinces of China in the 1970s, is associated with the occurrence of diseases such as cardiomyopathy (Keshan disease) and athropathy (Kashim-Beck disease), with potential reversal of these conditions with selenium supplementation (Keshan Disease Research Group; Rayman 2000). On the other hand, there is some suggestive evidence of potential adverse effects of selenium supplementation, such as an increased diabetes risk, in populations with high-selenium status. The association between selenium and cardio-metabolic outcomes is likely to be U-shaped, with potential harms
occurring at selenium levels both below and above the physiological range for optimal activity of selenoproteins (Stranges 2010a). Use of selenium enriched foods, supplements and fertilizers has increased markedly in recent years in the US and other Western countries (Broadley 2006; Millen 2004; Rayman 1997) because of the perception that the anti-oxidant properties of selenium could potentially reduce the risk of cancer, CVD and other chronic diseases. Given the recent findings on potential adverse effects of high selenium exposure (Laclaustra 2009a; Stranges 2007; Stranges 2010b), from a public health perspective the relationship between selenium status and CVD health should be clarified in order to help guide consumers in their choices of nutritional supplements and enriched food products. There has been no published systematic review on the effect of selenium only supplements on the primary prevention of CVD.

OBJECTIVES

1. To determine the effectiveness of selenium only supplementation to prevent cardiovascular disease (CVD) events.

2. To determine the effects of selenium only supplementation on cardiovascular risk factors (blood pressure, lipid levels) and adverse effects including type 2 diabetes.

METHODS

Criteria for considering studies for this review

Types of studies
Randomised controlled trials (RCTs)

Types of participants
Adults of all ages from the general population and those at high risk of CVD were included. The review focused on the effects of selenium supplementation on the primary prevention of CVD, and we have therefore excluded those people who have experienced a previous myocardial infarction (MI), stroke, revascularisation procedure (coronary artery bypass grafting (CABG) or percutaneous transluminal coronary angioplasty (PTCA)), those with angina or angiographically defined coronary heart disease (CHD).

Types of interventions
The intervention was selenium only supplementation, as a single ingredient. Multivitamin and mineral preparations including selenium were excluded as it would be impossible to disentangle selenium-specific effects from those derived from other micronutrients. Baseline selenium status is likely to influence the effect of selenium supplementation on cardiovascular outcomes (Rayman 2009; Rayman 2012; Stranges 2010a), so results were analysed by baseline selenium status and country, where possible, as well as by selenium dosage and duration of the intervention. Trials were only considered for inclusion where the comparison group was placebo or no intervention. We focused on follow-up periods of six months or more as these are most relevant for public health interventions, but length of follow-up was not an exclusion criteria. Only studies with at least three months follow-up were included in the meta-analyses. Very short term studies (less than three months follow-up) were dealt with descriptively.

Types of outcome measures

Primary outcomes
Major CVD end-points: CVD, non-fatal myocardial infarction (MI), non-fatal stroke, and revascularisation procedures (CABG or PTCA).

Secondary outcomes
- All cause mortality
- CHD composite end-point: fatal CHD, non-fatal MI, or CABG or PTCA
- Stroke composite end-point: fatal and non-fatal stroke
- Peripheral artery disease
- Type 2 diabetes*
- Changes in levels of blood pressure and blood lipids

* This outcome was used as a potential side effect of selenium. Other adverse effects were noted and data were collected on costs where available.

Search methods for identification of studies

Electronic searches
The following electronic databases were searched:
- Cochrane Central Register of Controlled Trials (CENTRAL) (Issue 10 of 12, October 2012) on The Cochrane Library;
- MEDLINE (Ovid) (1946 to week 2 October 2012);
- EMBASE Classic + EMBASE (Ovid) (1947 to 2012 Week 42);
• CINAHL (EBSCO) (to 24 October 2012);
• ISI Web of Science (1970 to 24 October 2012);
• PsycINFO (Ovid) (1806 to week 3 October 2012);
• Database of Abstracts of Reviews of Effects (DARE), Health Technology Assessment Database and Health Economics Evaluations Database (Issue 4 of 4, October 2012) on The Cochrane Library.

Medical subject headings (MeSH) or equivalent and text word terms were used. The Cochrane sensitive-maximising RCT filter (Lefebvre 2011) was used for MEDLINE and adaptations of it were used for EMBASE, Web of Science and PsycINFO. There were no language restrictions.

Searches were tailored to individual databases (Appendix 1).

Searching other resources
In addition, reference lists of reviews and retrieved articles were checked for additional studies.

We searched the metaRegister of controlled trials (mRCT) (www.controlled-trials.com/mrct), Clinicaltrials.gov (www.clinicaltrials.gov) and the World Health Organization (WHO) International Clinical Trials Registry Platform (ICTRP) (http://apps.who.int/trialsearch/) for ongoing trials (search date 5 November 2012). Citation searches were performed on key articles. Google Scholar was also used to search for further studies. Experts in the field were contacted for unpublished and ongoing trials. Authors were contacted, where necessary, for additional information.

Data collection and analysis

Selection of studies
From the searches, the title and abstract of each paper were reviewed by two review authors (KR, LH, NF or CD) and potentially relevant references retrieved. Following this initial screening, the full text reports of potentially relevant studies were obtained, and two review authors (KR, LH, NF or CD) independently selected studies to be included in the review using predetermined inclusion criteria. In all cases disagreements about any study inclusions were resolved by consensus and a third review author (SS) was consulted if disagreement persisted.

Data extraction and management
Data were extracted independently by two review authors (KR, LH) using a proforma and chief investigators were contacted to provide additional relevant information if necessary. Details of the study design, participant characteristics, study setting, intervention (including dose and duration), and outcome data including details of outcome assessment, adverse effects, and methodological quality (randomisation, blinding, attrition) were extracted from each of the included studies. Disagreements about extracted data were resolved by consensus.

Assessment of risk of bias in included studies
Risk of bias was assessed by examining the quality of the random sequence generation and allocation concealment, the description of drop-outs and withdrawals (including analysis by intention to treat), blinding (participants, personnel and outcome assessment) and selective outcome reporting (Higgins 2011). The risk of bias in included studies was assessed independently by two review authors (KR, LH).

Measures of treatment effect
Data were processed in accordance with the Cochrane Handbook for Systematic Reviews of Interventions (Higgins 2011). Dichotomous outcomes were expressed as relative risks (RR), and 95% confidence intervals (CI) were calculated for each study. For continuous variables net changes were compared (that is intervention group minus control group differences) and a weighted mean difference (WMD) and 95% CI were calculated for each study.

Assessment of heterogeneity
For each outcome tests of heterogeneity were carried out (using the Chi² test of heterogeneity and I² statistic). In the situation of no heterogeneity a fixed-effect model meta-analysis was performed. If substantial heterogeneity was detected the review authors looked for possible explanations for this (for example participants and intervention). If the heterogeneity could not be explained, the review authors considered the following options: to provide a narrative overview and not aggregate the studies at all, or use a random-effects model with appropriate cautious interpretation.

Subgroup analysis and investigation of heterogeneity
If there were sufficient trials that met the inclusion criteria, it was our intention to stratify results according to baseline selenium status and country, and selenium dosage. There were not sufficient trials for us to perform these analyses.

Sensitivity analysis
If there were sufficient trials that met the inclusion criteria, it was our intention to perform sensitivity analyses excluding studies of low methodological quality and to undertake funnel plots and tests of asymmetry (Egger 1997) to assess possible publication bias. There were not sufficient trials for us to perform these analyses.
RESULTS

Description of studies

See: Characteristics of included studies; Characteristics of excluded studies.

Results of the search

The searches generated 2225 hits, and 1656 after de-duplication. Screening the titles and abstracts, we identified 65 papers for formal inclusion or exclusion. One further trial was identified following contact with experts. Of these, 12 RCTs (14 papers) met the inclusion criteria; seven RCTs had a duration of three months or more and contributed to the meta-analyses. Five short term trials of selenium supplementation (less than three months) were dealt with descriptively. We did not identify any ongoing trials. The study flow diagram is presented in Figure 1.
Figure 1. Study flow diagram.

- 2,225 of records identified through database searching.
- 1 additional record identified through other sources (contact with experts).
- 1,656 of records after duplicates removed.
- 1,466 of records screened.
- 1,591 of records excluded.
- 66 of full-text articles assessed for eligibility.
- 12 studies (14 papers) included in qualitative synthesis.
- 6 studies included in quantitative synthesis (meta-analysis). 5/12 studies were less than 3 months duration and so were not included in meta-analyses, and 1 study did not provide data in a usable format.
Included studies

Details of the methods, participants, intervention, comparison group and outcome measures for each of the studies included in the review are shown in the Characteristics of included studies table. Twelve trials were included, with 19,715 participants randomised. Six trials recruited only male participants (17,843 randomised). Four trials (18,954 participants randomised) were conducted in the USA (Algotar 2010; Hawkes 2008; NCP; SELECT) and included the two largest trials, the Selenium and Vitamin E Cancer Prevention Trial (SELECT) with 17,448 participants randomised and the Nutritional Prevention of Cancer trial (NCP) with 1312 participants randomised. The remaining studies were conducted in Australia (Wu 2009), China (Yu 1990), Denmark (Ravn-Haren 2008), Finland (Luoma 1984), Norway (Meltzer 1994; Meltzer 1997), Spain (Navas-Carretero 2011) and the UK (UK PRECISE).

The duration of the intervention and follow-up periods varied enormously from a very short one and two weeks (Luoma 1984; Ravn-Haren 2008) to long term follow-up for the largest trials SELECT (SELECT) and NCP (NCP). Similarly, the dose of selenium supplementation that was used varied from 100 to 800 μg/day. Baseline selenium status varied by country, being lowest in China and highest in the USA. The country of recruitment, baseline plasma selenium level, dose of selenium supplementation and duration of the intervention for each study are shown in Table 1.

Studies were also variable in the participants recruited. One study was conducted in patients with prostate cancer, the Watchful Waiting Study (Algotar 2010). Two trials were conducted in participants at high risk of cancer, where CVD outcomes were secondary end-points (NCP; Yu 1990). Three trials were conducted in healthy populations where the focus was cancer prevention and CVD outcomes were secondary end-points (SELECT; UK PRECISE; Wu 2009). Six small trials focused on vascular function and oxidative defence (Hawkes 2008; Luoma 1984; Meltzer 1994; Meltzer 1997; Navas-Carretero 2011; Ravn-Haren 2008) with five of these being very short term (Luoma 1984; Meltzer 1994; Meltzer 1997; Navas-Carretero 2011; Ravn-Haren 2008).

Excluded studies

Details and reasons for exclusion for the studies that most closely missed the inclusion criteria are presented in the Characteristics of excluded studies table. Reasons for exclusion for the majority of studies included the use of multivitamin preparations including selenium rather than single selenium supplements, and no relevant outcomes.

Risk of bias in included studies

Details are provided for each of the included studies in the risk of bias tables in Characteristics of included studies.

Allocation

The methods of random sequence generation and allocation concealment were unclear in nine of the included studies. In the three studies where they were clear, the methods used were judged to be of low risk of bias (Hawkes 2008; NCP; UK PRECISE).

Blinding

Eleven of the 12 included studies stated that they were double blind (participants and personnel were blind to treatment allocation, as were outcome assessors) and were regarded at low risk of bias. In the remaining trial this was unclear (Meltzer 1994).

Incomplete outcome data

Most studies reported losses to follow-up and these were judged to have low risk of bias as the number of losses and reasons for loss to follow-up were similar across treatment arms. In three of nine studies this was judged unclear as losses to follow-up had not been reported (Algotar 2010) or a total number had been recorded and it was unclear from which treatment arm losses occurred (Hawkes 2008), or there was some differential loss due to adverse effects associated with higher selenium doses (UK PRECISE).

Selective reporting

For most studies the risk of bias associated with selective reporting was unclear, with the exception of two studies that clearly stated the primary and secondary outcomes and reported the results for these (Algotar 2010; Wu 2009). The largest trial focused on the effects of selenium in preventing the onset of cancer, where cardiovascular outcomes were secondary endpoints (SELECT). The two reports of the NCP trial reported secondary analyses and examined the outcomes of cardiovascular events and type 2 diabetes (NCP). A further trial stated that the non-specified outcomes were informed by the literature (UK PRECISE). It is unclear how these factors may have influenced reporting bias.

Other potential sources of bias

In most cases there was insufficient information to judge the risk of bias in other sources of bias not covered above, and all were categorised as unclear.
**Effects of interventions**

**Clinical events**

**Major CVD end-points**

The two largest trials had long term follow-up and reported clinical events (NCP; SELECT). The analyses were dominated by the SELECT trial, which carried over 80% of the weight. There were no statistically significant effects of selenium supplementation on CVD mortality (RR 0.97, 95% CI 0.79 to 1.2), non-fatal CVD events (RR 0.96, 95% CI 0.89 to 1.04) or all CVD events (fatal and non-fatal) (RR 1.03, 95% CI 0.95 to 1.11).

**Non-fatal strokes**

One study examined the effects of selenium supplementation on non-fatal strokes (SELECT). There was a reduction in all non-fatal strokes (ischaemic and haemorrhagic) with the intervention but this did not reach statistical significance (RR 0.79, 95% CI 0.58 to 1.07). Similarly, no statistically significant effects were seen with selenium supplementation for ischaemic and haemorrhagic strokes reported separately.

**All cause mortality**

The two largest studies also reported all cause mortality (NCP; SELECT). There were no statistically significant effects of selenium supplementation on all cause mortality (RR 0.97, 95% CI 0.88 to 1.08).

**Cardiovascular risk factors**

Nine of 12 trials measured lipid levels, but only three trials (six trial arms) contributed to the meta-analysis (Hawkes 2008; Wu 2009; UK PRECISE). The five short term trials of less than three months (Luoma 1984; Meltzer 1994; Meltzer 1997; Navas-Carretero 2011; Ravn-Haren 2008) were not included in the pooled analysis, and a further trial had follow-up data and did not include change from baseline (Yu 1990). Results from these studies have been dealt with in a narrative fashion.

From the pooled analysis, selenium supplementation reduced total cholesterol but this did not reach statistical significance (WMD - 0.11 mmol/L, 95% CI - 0.3 to 0.07). There was no effect of selenium supplementation on high density lipoprotein (HDL) levels (WMD 0.01 mmol/L, 95% CI - 0.066 to 0.08). Non-HDL cholesterol was measured in one trial of varying doses of selenium supplementation (UK PRECISE). Pooling these data showed a statistically significant reduction in non-HDL cholesterol (WMD - 0.2 mmol/L, 95% CI - 0.41 to 0.00). Similarly there was a reduction in low density lipoprotein (LDL) cholesterol in the one trial where this was measured (Hawkes 2008) but this did not reach statistical significance (WMD - 0.18 mmol/L, 95% CI - 0.54 to 0.18). There was no effect of selenium supplementation on triglycerides in the one trial that measured this outcome (Hawkes 2008).

Four short term studies showed no effect of short term supplementation on lipid levels (Luoma 1984; Meltzer 1994; Navas-Carretero 2011; Ravn-Haren 2008). A further short term study showed no change in total and LDL cholesterol or triglycerides with selenium supplementation, but a 12% (P < 0.05) increase in HDL cholesterol (Meltzer 1997). In the study in Chinese tin miners where only follow-up data were available, there was no effect of selenium supplementation on total cholesterol levels (Yu 1990).

One short term study measured blood pressure and found no effect of selenium supplementation (Navas-Carretero 2011). None of the longer term (three months plus) studies examined the effects of selenium supplementation on blood pressure levels.

**Adverse effects**

The effect of selenium supplementation on the risk of type 2 diabetes was measured in three trials (four trial arms, 18,790 participants randomised). There was a small increased risk of type 2 diabetes with selenium supplementation but this did not reach statistical significance (RR 1.06, 95% CI 0.97 to 1.15). The results were dominated by the SELECT trial, which carried 95% of the weight. The UK PRECISE trial measured plasma adiponectin as an independent risk factor of type 2 diabetes. After six months of supplementation, they found no effect of selenium supplementation on adiponectin levels.

Other adverse effects of selenium supplementation were noted in the included studies and are presented in Table 2. The SELECT trial found a significantly increased risk of alopecia (RR 1.28, 95% CI 1.01 to 1.62) and dermatitis grade 1 to 2 (RR 1.17, 95% CI 1.0 to 1.35) with selenium supplementation.

**DISCUSSION**

The aim of this review was to evaluate the effectiveness of selenium supplementation, as a single ingredient, for the primary prevention of CVD. We also examined the effects of selenium only supplementation on major CVD risk factors, including blood lipids and blood pressure, as well as on potential adverse cardio-metabolic effects such as type 2 diabetes, which has been previously indicated by two individual trials (NCP; SELECT).

**Summary of main results**
There were no statistically significant effects of selenium supplementation on major CVD clinical end-points, such as all cause mortality and cardiovascular mortality, or on overall non-fatal cardiovascular disease including CHD and stroke. There was a suggestion of a potential reduction in all non-fatal strokes (ischaemic and haemorrhagic) with the selenium supplementation in one trial (SELECT), which however did not reach statistical significance. With regard to CVD risk factors, current trial evidence suggests a potential beneficial effect of selenium supplementation on blood lipids, namely non-HDL cholesterol; for total and HDL cholesterol as well as for triglycerides the findings did not reach statistical significance. Surprisingly, no trial has to date examined the effect of selenium supplementation alone on blood pressure end-points. Findings from the pooled analysis did not show a statistically significant increased risk of type 2 diabetes with single selenium supplements. These analyses were largely dominated by the SELECT trial (SELECT), which only recruited male participants and did not provide results by the baseline selenium status, unlike the NPC findings (NCP). In subgroup analyses within the NPC trial, there was a significant increased risk of type 2 diabetes only among participants with high baseline plasma selenium (hazard ratio of 2.70 in the highest tertile of plasma selenium, that is > 121.6 ng/ml). However, results of this review also highlight major gaps in the published literature. There is still a lack of definitive evidence on the effects of selenium only supplementation on CVD clinical events, lipid levels and type 2 diabetes, and for the primary prevention of CVD. More trial evidence is especially needed to clarify potential benefits of selenium supplementation on blood lipids, as shown by the PRECISE trial findings (UK PRECISE), as well as potential adverse effects of selenium supplementation on development of type 2 diabetes, as suggested by secondary analyses of the NPC trial (NCP).

**Overall completeness and applicability of evidence**

Twelve trials (seven of at least three months duration and contributing to the meta-analyses) were included, with 19,715 participants randomised. However, only the two largest trials (NCP; SELECT) contributed data to our primary outcomes, that is major CVD clinical end-points. Also, the vast majority of participants that were included were from these two trials, whereas the other included studies comprised a much smaller number of participants and only examined the effect of selenium supplementation on CVD risk factors or its potential adverse effects on fasting glucose levels. Six trials recruited only male participants, including SELECT, which provided the vast majority of data to this review. Therefore, the applicability of these findings to the female population is uncertain given the suggested gender differences in the response of selenoprotein biomarkers to selenium supplementation (Méplan 2007; Rayman 2012) as well as the well-established differences in cardio-metabolic risk factor profiles between women and men (Mosca 2011).

The large majority of individuals randomised (18,954 out of 19,715, over 96% of total participants) came from studies based in the US, a selenium-replete population. Hence, the applicability and relevance of these findings to the effect of selenium supplements in populations with lower dietary selenium intake and suboptimal or deficient selenoprotein status are uncertain. Indeed, current recommendations for dietary selenium intake (55 to 75 µg/day) are based on optimising the activity of selenoproteins, namely glutathione peroxidases (GPx) (Rayman 2012), which require a plasma selenium concentration around 90 µg/L (Burk 2006; Duffield 1999; Xia 2005). However, the selenium dietary intake and selenium concentration required for optimal selenoprotein P activity are likely to be higher (Hurst 2010; Xia 2010). The vast majority of the US population (99%) have blood selenium concentration well above 95 µg/L based on data from the National Health and Nutrition Examination Survey (NHANES), 2003 to 2004 (Laclaustra 2009b; Laclaustra 2010). It is therefore plausible that the average American participant randomised in these selenium supplementation trials would have had replete selenoprotein status, at least as far as GPx activities. Health benefits of additional selenium intake in the US population are questionable and adverse effects, such as an increase in diabetes risk, are possible (Stranges 2010a). In fact, accumulating evidence seems to point out that the association between selenium and cardiometabolic health is likely to be U-shaped, with potential harms occurring at levels of selenium status both below and above the physiological range for optimal activity of selenoproteins (Rayman 2012; Stranges 2010a). Furthermore, the duration of selenium supplementation and follow-up periods varied largely across studies, from the very short intervention of one and two weeks (Luoma 1984; Ravn-Haren 2008) to long term supplementation and follow-ups for the largest trials, SELECT (Klein 2011; Lippman 2009) and NCP (Stranges 2006; Stranges 2007). Both short and long term health effects of selenium supplements are plausible given the relatively quick response of selenium biomarkers and selenoproteins to selenium supplementation within the time range of 12 to 20 weeks (Burk 2006; Duffield 1999; Hurst 2010; Xia 2005; Xia 2010) as well as the observed beneficial effect of a relatively short term (six months) selenium supplementation on blood lipid profiles (UK PRECISE). However, it is likely that any beneficial or detrimental effect of selenium supplements in terms of major chronic disease end-points, such as mortality, CVD and type 2 diabetes, would represent the outcome of a long term process linked to a sustained effect by the interplay of selenium status with genetic and environmental factors (Rayman 2012; Stranges 2010a). Therefore, the public health relevance of selenium supplementation trials with extremely short term interventions or follow-up periods is highly questionable in this context. However, this review was largely dominated by two trials, SELECT and NPC, which also had the longest periods of
intervention and follow-up (NCP; SELECT), hence their results can be considered reliable in terms of potential health impact of selenium supplementation.

In the included trials, the dose of selenium supplementation used varied from 36 to 800 µg/day, the baseline selenium status varied by country, being lowest in China and highest in the US, and the chemical forms of selenium supplements used varied. The largest trials used either selenomethionine (SELECT) or selenium yeast (NPC; PRECISE), which are considered to be the most effective forms of selenium supplementation. Indeed, selenomethionine, the organic form of selenium, has been shown to have nearly twice the bioavailability of selenium as compared to inorganic selenium compounds (Burk 2006; Xia 2005). Again, the null results from both SELECT and NPC with regard to CVD endpoints come from selenium-replete populations, in which most selenoproteins would already have been optimised at baseline. Therefore their participants would have been unlikely to experience any additional increase in selenoprotein activities as a result of selenium supplementation (Rayman 2012; Stranges 2010a).

Finally, studies were also variable in the nature of participants recruited. The NPC trial was conducted among participants with a confirmed history of non-melanoma skin cancer (NCP); the Watchful Waiting Study was based on prostate cancer patients (Algotor 2010); and one trial recruited participants at high risk of cancer (Yu 1990). Other trials were conducted in healthy populations with a focus on cancer prevention, or were pilot studies to assess the feasibility of larger trials (SELECT; UK PRECISE; Wu 2009). In all these included trials, CVD clinical outcomes or risk factors were secondary end-points. Six small trials focused on vascular function and oxidative defence (Hawkes 2008; Luoma 1984; Meltzer 1994; Meltzer 1997; Navas-Carretero 2011; Ravn-Haren 2008) with five of these being very short term (Luoma 1984; Meltzer 1994; Meltzer 1997; Navas-Carretero 2011; Ravn-Haren 2008). Therefore, the overall applicability and relevance of these findings to the effectiveness of selenium supplements for CVD primary prevention in the general population or in high risk individuals for CVD is questionable, given that no trial has been specifically designed to examine the effect of selenium supplements on major CVD outcomes as the primary end-points.

**Quality of the evidence**

The two largest trials contributing to this review, SELECT and NPC, were primarily cancer prevention trials conducted in the US, a selenium-replete population; CVD clinical outcomes or potential adverse effects such as type 2 diabetes were secondary endpoints (NCP; SELECT). Furthermore, the largest trial examining the effect of selenium supplementation on blood lipids was conducted in a group of relatively healthy elderly people, aged 60 to 74 years, recruited from four general practices in different parts of the UK; blood lipids were measured in frozen non-fasting blood samples as secondary non-prespecified outcomes (UK PRECISE).

The other studies included were small trials which only marginally contributed to this review. Obviously, there are concerns about the robustness of results from secondary end-points or subgroup analyses of clinical trials, especially with regard to the potential usefulness of these results to inform public health guidelines or clinical recommendations (Brookes 2004; Freemantle 2001). Therefore, caution is needed in the interpretation of findings from post hoc analyses of clinical trials and secondary end-points, such as CVD outcomes and type 2 diabetes in SELECT and NPC or blood lipids in the UK-PRECISE trial, given the intrinsic limitations and potential biases of such an approach.

Specifically, in both NPC and SELECT diagnosis of type 2 diabetes was based on self-report or use of diabetes medication rather than on biomarker data. This may have led to some misclassification (under-diagnosis) of diabetes at baseline or during the trials. However, given the randomised design and blinding, differential misclassification according to treatment assignment is unlikely. It should be noted that the effect of non-differential misclassification would probably be to underestimate the true relative risk and decrease the statistical power of these studies (Copeland 1977).

Likewise, CVD incidence and mortality were not primary endpoints in either the SELECT or the NPC trial. Therefore, findings must be cautiously interpreted as they result from secondary analyses. However, in both studies the ascertainment of the CVD end-points did not change throughout the entire blinded phase of the trial. In addition, the selected CVD end-points are all hard clinical outcomes and should be less subject to diagnostic misclassification. With regard to the results from the PRECISE trial (UK PRECISE), blood lipids were measured in frozen plasma samples that were collected in the non-fasting state so that only total and HDL cholesterol concentrations could be measured, while triglyceride levels were not.

Furthermore, although CVD incidence and mortality risk estimates as well as other selected outcomes in these trials were adjusted for a wide range of potential confounders, there was a lack of information on some important variables at baseline, such as family history of diabetes or other CVD risk factors, in some of these trials (NPC, SELECT). However, randomisation should have minimized the impact of potential confounding by unmeasured risk factors.

A further limitation of the evidence to date concerns the generalisability of results from the major trials contributing to this review (NPC; PRECISE; SELECT) to the general public and specific population subgroups, because of the selective nature of the participants randomised in these trials. Specifically, SELECT recruited only male participants from a selenium-replete population. Therefore, the applicability of SELECT findings to the female gender or to populations with lower dietary selenium intakes and suboptimal or deficient selenoprotein status is uncertain. The NPC trial sample consisted of elderly individuals (mean age: 63.2 years) from the eastern USA who had a history of non-melanoma skin cancer. The generalisability of the NPC findings to other population...
subgroups may therefore be limited. Finally, the PRECISE trial sample was based on a group of relatively healthy elderly, mostly white volunteers, aged 60 to 74 years, recruited from four general practices in different parts of the UK. Again, the generalisability of PRECISE findings to younger adults or to other population subgroups is uncertain. Altogether, the relatively selective nature of participants in these trials makes the generalisability of the evidence to date questionable.

Potential biases in the review process

We decided to restrict our review to clinical trials in which the intervention was selenium only supplementation, as a single ingredient. Multivitamin and mineral preparations including selenium were excluded as it would have been impossible to disentangle selenium-specific effects from those derived from other micronutrients. While this restriction avoids the potential impact of confounding by other ingredients in multivitamin and mineral supplements, it does not allow us to examine the potential interaction of selenium with other micronutrients, which is plausible both statistically and biologically (SELECT).

It should be noted, however, that other RCTs which have examined the effect of selenium in combination with other vitamins or minerals on CVD end-points have also yielded inconclusive findings (Brown 2001; Hercberg 2004; Korpela 1989; Kuklinski 1994; You 2001). Obviously, the restriction to trials using selenium only supplementation prevented the inclusion of important studies, primarily the large SU.VI.MAX (SUpplementation en Vitamines et Minéraux AntioXydatants) trial in France, which would have boosted the statistical power of our pooled analyses for the selected outcomes.

Agreements and disagreements with other studies or reviews

A number of observational studies have examined the association between selenium status and risk of CVD across different populations. The overall observational evidence is suggestive of a possible U-shaped association between selenium and CVD risk (Bleys 2008; Bleys 2009; Salonen 1982; Virtamo 1985; Wei 2004), but with a large degree of inconsistency across studies. This is likely to be explained by the large variability in dietary selenium intakes and selenium status in different regions and populations around the world (Rayman 2012; Stranges 2010a). Moreover, a previous meta-analysis of 14 cohort studies found a modest inverse association between biomarkers of selenium status, such as blood or toenail selenium concentrations, and the risk for coronary heart disease (Flores-Mateo 2006). However, results from this early meta-analysis of the few randomised trials examining the effect of selenium supplementation on cardiovascular outcomes were inconclusive. Likewise, other randomised trials which have examined the effect of selenium supplements in combination with other vitamins or minerals on CVD end-points have been inconclusive (Hercberg 2004; You 2001). Results from the present review, which incorporates recent findings from the large SELECT trial, are in agreement with previous evidence and do not support a role for selenium supplementation in the primary prevention of CVD at the present time, especially among those individuals with adequate-to-high selenium status.

With regard to the effect of selenium supplementation on CVD risk factors, in addition to the studies included in this review, few other trials have examined the effect of selenium supplementation in combination with other micronutrients on blood lipids. For example, in the SU.VI.MAX trial, long term daily supplementation with a combination of antioxidants including selenium (100 µg/day as high-selenium yeast) increased serum triglyceride levels compared to supplementation with placebo (Hercberg 2005). Likewise, in a randomised trial in a rural Chinese population with a low dietary intake of selenium, long term combined supplementation with selenium (37.5 µg), vitamin C and vitamin E resulted in small but significant increases in total and LDL cholesterol levels, although HDL concentrations were not affected (Zhang 2006). In partial disagreement with this previous evidence, results from the PRECISE trial suggest a potential beneficial effect of selenium supplementation on blood lipids, with a significant reduction in non-HDL cholesterol concentrations. However, the clinical significance and potential implications of these findings for CVD prevention are unclear given the overall lack of effect of selenium supplementation on major CVD end-points, as also shown by this review. Data from randomised studies on the effect of selenium only supplementation on other CVD risk factors, such as blood pressure, are lacking.

Evidence from observational studies and RCTs on selenium and diabetes is conflicting. Early findings from the NPC trial and observational cross-sectional studies (NHANES) from the selenium-replete US population were suggestive of a potential increased risk of type 2 diabetes with high selenium status or selenium supplementation (Bleys 2007; Laclaustra 2009b; NCP). However, results from the SELECT trial did not show a significant increased risk of type 2 diabetes with single selenium supplements, with a tendency to null findings with increasing duration of follow-up (SELECT). Recently, a pooled longitudinal analysis from two US cohorts showed inverse associations between toenail selenium levels and the incidence of type 2 diabetes, with a reducing diabetes risk across quintiles of toenail selenium (Park 2012).

In other populations with dietary selenium intakes or selenium status lower than in the USA, such as in Europe, the evidence linking selenium to diabetes risk is also inconsistent (Rayman 2012; Stranges 2010a). For example, in the French SU.VI.MAX trial after 7.5 years of follow-up, no effect on fasting plasma glucose was observed for a combined supplementation with anti-oxidant micronutrients including selenium (100 µg/day as high-selenium yeast) despite a positive association between glucose and selenium.
concentrations at baseline in the whole population (Czernichow 2006). Overall, these discrepant results remain unexplained although there is convincing biological evidence on the potential role of selenoproteins, such as glutathione peroxidases (GPx1) and selenoprotein P (SEPP1), in glucose metabolism and insulin resistance (Rayman 2012; Stranges 2010a). Both low and high levels of expression of these selenoproteins have been shown to promote development of type 2 diabetes in animal models (Labunskyy 2011), which might partly explain the apparent U-shaped association between selenium status and diabetes risk (Rayman 2012; Stranges 2010a). In line with recent evidence, namely from the SELECT trial, pooled analyses from the present review did not show a significant increased risk of type 2 diabetes with single selenium supplements.

**AUTHORS’ CONCLUSIONS**

**Implications for practice**

Selenium is commonly added to several multivitamin and mineral preparations and enriched foods that are widely used by the general public in many Western countries because it is recognised as an essential trace element for maintaining optimal health status. Its use is also a result of aggressive marketing. Results from the present review, based on a small number of available clinical trials, do not support a role for selenium supplementation in the primary prevention of CVD at the present time, especially in those individuals and populations with adequate-to-high selenium status. Current trial evidence mostly comes from US-based studies, where the average selenium status and dietary selenium intakes are above the levels recommended for optimal activities of selenoproteins (that is a selenium concentration around 90 µg/L and dietary selenium intake of 55 to 75 µg/day, respectively) (Rayman 2012). Health benefits of additional selenium intake from supplementation are therefore unlikely in such populations. In line with this notion, recent findings from the SELECT trial did not support a role of selenium supplementation in cancer prevention among healthy male individuals from the US and Canada, two selenium-replete populations, with a median baseline serum selenium concentration of 136 µg/L (SELECT).

Unfortunately, there is very limited trial evidence on the effect of selenium only supplementation on CVD outcomes in populations with lower selenium status and selenium dietary intakes than in the US. The few non-US trials are based on small samples or short duration of intervention and follow-up; not one of these trials has examined the effect of selenium supplements on CVD clinical end-points. Only the UK-PRECISE trial, with a fairly sizable sample, examined the effect of a six month supplementation with 100, 200 or 300 µg selenium/day as high-selenium yeast, compared to placebo, among 501 elderly volunteers with a mean plasma selenium concentration at baseline of 88.8 ng/ml (equivalent to 91.2 µg/L) (UK PRECISE). In this trial, supplementation at 100 and 200 µg selenium/day lowered total serum cholesterol and non-HDL cholesterol; the 300 µg/day dose had no significant effect on total or non-HDL cholesterol but raised HDL cholesterol significantly. In addition, the total-HDL cholesterol ratio decreased progressively with increasing selenium dose (UK PRECISE). Pooled analyses from the present review showed a statistically significant reduction in non-HDL cholesterol with selenium supplementation. While the potential implications of these findings for cardiovascular disease prevention are unclear, potential benefits of selenium supplementation are plausible only in populations with suboptimal or insufficient selenoprotein status. Moreover, these findings corroborate the notion that the association between selenium and cardio-metabolic outcomes is likely to be U-shaped, with potential harms occurring at selenium levels both below and above the range for optimal activity of selenoproteins (Rayman 2012; Stranges 2010a).

Results from the present review did not show a statistically significant increased risk of type 2 diabetes with single selenium supplements but, given the limited evidence to date, an increased risk of diabetes with selenium supplementation cannot be ruled out. The limited trial evidence to date synthesised in this review does not support the use of selenium supplements in the primary prevention of cardiovascular disease. In particular, the indiscriminate and widespread use of selenium supplements in individuals and populations with adequate-to-high selenium status is not justified and should not be encouraged.

Obviously, there are specific population subgroups affected by conditions predisposing to selenium deficiency that might therefore benefit from selenium supplementation. For example, the potential effectiveness of selenium supplementation among individuals in areas with endemic low selenium in the soil, or among certain ethnic subgroups with poor anti-oxidative capacity, or in patients with chronic conditions (for example HIV, chronic kidney disease) warrants further investigation (Fairweather 2011).

**Implications for research**

There is a lack of trial evidence on potential effects of selenium only supplementation specifically designed to mitigate cardiovascular disease (CVD) outcomes across a wider range of selenium concentration, especially in populations with suboptimal or insufficient selenoprotein status. Randomised trials in participants across a wider range of selenium status would help determine the optimal levels of selenium intake in the general population, to maximise health benefits whilst avoiding potential chronic toxic effects. Also, optimal intake for any individual is likely to depend on polymorphisms in selenoprotein genes that may also affect the risk of disease, including coronary heart disease and ischaemic stroke (Alanne 2007; Rayman 2012). Future work in the field examining the effect of selenium supplements on CVD risk should also give
attention to the potential interaction between genetic make-up and selenium intake or status. Further trial evidence with a larger representation of women is also desirable given the well-known differences in cardio-metabolic risk factor profiles between women and men (Mosca 2011) and the suggested gender differences in the response of selenoprotein biomarkers to selenium supplementation (Méplan 2007). Finally, additional evidence is needed to clarify the link between selenium status and supplementation with metabolic effects on blood lipids and diabetes risk, and in more detail across different ranges of selenium concentration and dietary selenium intakes, as well as potential underlying mechanisms.

### Allocation concealment (selection bias)

**High risk**
Randomised in pairs, one from each pair assigned by coin flip

### Blinding of participants and personnel (performance bias)

**Low risk**
States double blind

### Blinding of outcome assessment (detection bias)

**Low risk**
States double blind

### Incomplete outcome data (attrition bias)

**Unclear risk**
Some losses to follow-up (12/54), unclear from which group

### Selective reporting (reporting bias)

**Unclear risk**
Not all outcomes are presented in the results

### Other bias

**Unclear risk**
Insufficient information to judge

---

**Luoma 1984**

**Methods**
RCT of parallel group design

**Participants**
27 healthy medical students from Finland (9 males, 18 females), mean age 24 years. Baseline selenium status 73.7 (14) µg/L in the intervention group, 75.1 (15.4) µg/L in the control group

**Interventions**
Daily selenium supplementation of 96 µg selenium yeast tablets for 2 weeks. Control group received yeast tablets without selenium. Follow-up at the end of the intervention period of 2 weeks

**Outcomes**
Total cholesterol, HDL cholesterol, triglycerides

**Notes**
Focus of the trial was to examine the relationship between serum selenium levels and glutathione peroxidase activity and lipids connected with atherogenesis. Very short term trial

### Meltzer 1994

**Methods**

RCT of parallel group design

**Participants**

Healthy students or employees at the Institute of Nutrition Research, University of Oslo. Participants were not taking medication, were not pregnant or lactating, and had not taken mineral containing supplements within 3 months of the study. 32 participants (2 male) were randomised to 3 arms. Age ranged from 21-56 years

**Interventions**

The intervention group (n=11) ate selenium enriched bread (70µg selenium per 90g of bread - 3 slices). Mean selenium intake was 135 (25)µg/day. The control group (n=10) ate their normal diet (mean selenium intake 77(25) µg/day). The intervention period was 6 weeks

**Outcomes**

LDL and HDL cholesterol.

**Notes**

3 arm trial, fish (containing selenium, arsenic and mercury), selenium enriched bread and a control arm. We have just used the selenium enriched bread as the intervention group. Short term study
Incomplete outcome data (attrition bias) | Unclear risk | No losses to follow-up reported
---|---|---
Selective reporting (reporting bias) | Unclear risk | Insufficient information to judge
Other bias | Unclear risk | Insufficient information to judge

**Meltzer 1997**

**Methods**
RCT of parallel group design

**Participants**
Healthy female students from the Institute of Nutrition Research, University of Oslo. Participants were not taking medication, were not pregnant or lactating, and had not taken vitamin, mineral or fatty acid containing supplements within 3 months of the study. 32 participants were randomised to 3 arms. Mean age 23.5 (3.4) years

**Interventions**
The intervention group (n=7) ate selenium enriched bread (115µg selenium per 90g of bread - 3 slices) and placebo oil capsules. Mean selenium intake was 185 (27) µg/day. The control group (n=8) ate their normal diet with placebo oil capsules and placebo bread (mean selenium intake 77(25) µg/day). The intervention period was 6 weeks.

**Outcomes**
Total, LDL and HDL cholesterol and triglycerides.

**Notes**
Two intervention arms - PUFA capsules and selenium enriched bread. We have just used the selenium enriched bread group. Short term study

**Risk of bias**

Navas-Carretero 2011

Methods
RCT of parallel group design

Participants
Healthy participants, men and women aged 20-45 years with a BMI between 18.5 and 30. Participants were not taking any medication and were not following any dietary treatment, and had maintained their weight for the last 3 months (±3 kg). Exclusion criteria included metabolic diseases such as diabetes, thyroid impairments and other endocrine disturbances, hypertension, gastric and peptic ulcers, constipation or diarrhoea. 24 participants randomised

Interventions
The intervention group received an isocaloric moderately high protein diet (30% of energy) including consumption of 200g chicken breasts enriched with selenium four times a week (25.5µg/100g). The control group ate the same diet but the chicken breasts were not enriched with selenium (6.5µg/100g). The intervention period lasted for 10 weeks

Outcomes
Lipid levels, blood pressure.

Notes
The focus of the study was on high protein diets for weight loss and antioxidant support from selenium. Short term study

**NCP**

**Methods**

Stranges 2006 and Stranges 2007 - Secondary analysis of the blinded phase (1983-96) of the Nutritional Prevention of Cancer (NCP) trial among participants free of CVD or type 2 diabetes at baseline respectively. The NCP was a double blind parallel group RCT.

**Participants**

Inclusion criteria for the NCP trial: participants recruited from 7 dermatology clinics in low selenium areas in Eastern United States. Subjects were eligible if they had confirmed histories of non-melanoma skin cancers within the year prior to randomisation, an estimated 5 year life expectancy and had no reported internal cancer within the previous 5 years. Exclusion criteria were kidney and liver disorders.

Stranges 2006 - 1004 participants from 1316 had a valid baseline selenium value and were free of CVD at baseline (504 from the selenium group and 500 from the placebo group).

Stranges 2007 - 1202 participants from 1316 had a valid baseline selenium value and were free of type 2 diabetes at baseline (600 from the selenium group and 602 from the placebo group).

71% of participants were males and baseline selenium status was 113 µg/L.

**Interventions**

Daily supplementation of 200 µg high selenium yeast or a yeast placebo. Mean follow-up period was 7.6 years.

**Outcomes**

Stranges 2006 - all cardiovascular disease, all coronary heart disease, all cerebrovascular disease, cardiovascular disease mortality, total mortality.

Stranges 2007 - type 2 diabetes.

**Notes**

**Selective reporting (reporting bias) | Unclear risk | Secondary analysis of a cancer prevention study, so not the original pre-specified outcomes of the NCP trial**

**Other bias | Unclear risk | Secondary analysis of a cancer prevention study, so not the original pre-specified outcomes of the NCP trial**

---

**Ravn-Haren 2008**

**Methods**

RCT crossover design (analysed as parallel group 1 week for each intervention, 4 weeks follow-up, 8 weeks washout between interventions)

**Participants**

20 healthy men aged 18-40 years (mean 26.8) recruited by advertising at local Universities in the Copenhagen area. Smoking, obesity (BMI>30), family history of chronic disease, use of any medication, heavy physical activity (>10 hours per week), high intake of fish (>2 times per week), and use of vitamin and mineral supplements 2 weeks before the trial or selenium supplements 8 weeks before the trial were exclusion criteria. Baseline selenium status across the 3 intervention groups and placebo group ranged between 107 and 114 µg/L

**Interventions**

Subjects supplemented their usual diet with one of 4 test meals 8 weeks apart. On the first day of each intervention period the subjects were served a standardised breakfast (with the test meal) and a standardised lunch at the University. Subjects were not allowed to consume other foods during their stay except water. On the second day they were served the test meal with breakfast and were supplied with 5 L of frozen milk and 5 tablets for the last days of the intervention week. The 4 test meals consisted of 1 L of milk (selenium enriched or control milk) and a tablet (selenium enriched yeast, selenate or placebo). Selenium enriched milk (480 µg selenium/day) was given with a placebo tablet and control milk with selenium enriched yeast (300 µg selenium/day), selenate (300µg selenium/day) or placebo tablets. The follow-up period for each intervention was 4 weeks

**Outcomes**

Total cholesterol, LDL and HDL cholesterol and triacylglyceride (TAG)

**Notes**

Very short term study - 1 week intervention period for each intervention, 4 weeks follow-up

### SELECT

**Methods**
Multicentre RCT of parallel group design - The Selenium and Vitamin E Cancer Prevention Trial (SELECT)

**Participants**
35,533 men from 427 participating sites in the US, Canada and Puerto Rico randomised to 4 arms - selenium, vitamin E, selenium and vitamin E, placebo. Eligibility criteria: men aged 55 years or more (50 plus for African Americans) with no prior prostate cancer and digital rectal examination not suspicious for cancer. No current use of anticoagulation therapy other than 175mg/day or less of aspirin or 81mg/day aspirin with clopidogrel bisulphate. No history of stroke and normal BP also required. 8910 men were randomised to receive selenium and 8856 men were randomised to receive placebo. Median age 62.6 years (range 58-68), 79% white, 12% African American, 7% Hispanic, 2% other. Baseline selenium status 135 (range 123.4 to 145.9) µg/L in the intervention group, 137.6 (range 124.7 to 151.8) µg/L in the placebo group

**Interventions**
Daily selenium supplementation of 200 µg L-selenomethionine (1 selenium tablet, one placebo tablet) or placebo (2 placebo tablets). Mean follow-up period 5.46 years (Lippman 2009) and 7-12 years (Klein 2011)

**Outcomes**
Lippman 2009 - CVD mortality, CVD events (any including death), non-fatal stroke
Klein 2011 - all cause mortality, non-fatal CVD events, diabetes

**Notes**
Data only used from the selenium only and placebo arms. Focus of the trial was to examine the effects of selenium and vitamin E in the prevention of prostate cancer and other diseases in relatively healthy men

### UK PRECISE

#### Methods

RCT of parallel group design

#### Participants

Healthy older people recruited from 4 general practices in the UK affiliated with the MRC General Practice Research Framework. Recruited similar numbers of men and women from each of 3 age groups 60-64, 65-69 and 70-74 years. Exclusion criteria: Southwest Oncology Group performance score of >1 (i.e. incapable of carrying out light housework or office work), active liver or kidney disease, a previous diagnosis of cancer, diagnosed HIV infection, receipt of immunosuppressive therapy at recruitment, diminished mental capacity, or receipt of selenium supplements 50µg selenium/day, in the previous 6 months. 501 participants were randomised, mean age 67.4 years and mean baseline selenium of 88µg/L.

#### Interventions

After a 4 week placebo run in phase, 501 participants were randomised in equal numbers to receive one of 4 treatment regimes: placebo or 100, 200 or 300µg per day for at least 6 months. The intervention agent was the high selenium yeast SelanoPrecise or an identical placebo yeast. Participants were followed up at 6 months.

#### Outcomes

Lipid levels

#### Notes

Pilot study to determine recruitment, retention and adherence (prespecified primary outcomes) to inform the PRECISE trial which was never funded. Non specified outcomes (lipid levels) were informed by the literature.

<th>Methods</th>
<th>RCT of parallel group design</th>
</tr>
</thead>
</table>

####Participants

Healthy older males aged 40-70 yrs recruited in or near Adelaide Australia via adverts in local papers and electronic media in 2004. Exclusion criteria were cancer patients undergoing chemotherapy or radiotherapy, those with a sensitivity to the study foods (e.g. gluten/wheat intolerance), those unable to comply with the protocol and those not available for all follow-up periods. Men currently supplementing with selenium or supplementing above recommended daily intakes for folate and/or vitamin B12 and/or vitamin C were also excluded. 179 men were eligible and were screened for plasma selenium levels, the 81 men with the lowest selenium levels were randomised into 3 dietary groups: CONTROL, BIOFORT and PROFORT, depending on the wheat source of the biscuits they were required to consume. 27 men randomised to each group, mean age 56 years, mean baseline selenium 122 µg/L.

####Interventions

Trial participants were required to consume 1 biscuit per day for the first 8 weeks, 2 biscuits per day for the second 8 weeks and 3 biscuits per day for the third 8 weeks. Each BIOFORT and PROFORT biscuit would provide approximately 75 µg/day so the daily amount of selenium from the biscuits would increase from 75 to 150 to 225µg/day in the two intervention arms. The control group received low selenium biscuits. The BIOFORT biscuits used bio fortified wheat and the PROFORT biscuits acted as a positive control and used process fortified wheat. Follow-up was at the end of the intervention period of 24 weeks.

####Outcomes

Lipid levels

####Notes

CONTRIBUTIONS OF AUTHORS

All authors contributed to the protocol development. The trials search co-ordinators of the Cochrane Heart Group ran the searches; KR, LH, NF or CD screened titles and abstracts, assessed studies for formal inclusion or exclusion and abstracted data. KR and LH assessed methodological quality. KR conducted the analysis, and wrote the first draft of the methods and results sections; SS wrote the first draft of the background and discussion sections. All authors contributed to later drafts.

DIFFERENCES BETWEEN PROTOCOL AND REVIEW
It was our intention to examine effects of interventions by stratified analyses to explore the impact of different selenium doses, duration of the intervention, baseline selenium status and country, but there are currently insufficient available trials to do this. Similarly there are insufficient trials to date to perform sensitivity analyses and funnel plots to explore the effects of methodological quality and publication bias. In the protocol we stated that we would focus on studies of six months or more follow-up as these are most relevant for public health interventions. We did not have a minimum period of follow-up for inclusion. We have revised this to examine studies of three months or more follow-up in meta-analyses, where appropriate, and have dealt with shorter term studies descriptively.
