Measurements of the branching fractions of the decays $B^0_s \rightarrow D^\mp_s K^\pm$ and $B^0_s \rightarrow D_s^- \pi^+$

The LHCb collaboration

ABSTRACT: The decay mode $B^0_s \rightarrow D^\mp_s K^\pm$ allows for one of the theoretically cleanest measurements of the CKM angle $\gamma$ through the study of time-dependent $CP$ violation. This paper reports a measurement of its branching fraction relative to the Cabibbo-favoured mode $B^0_s \rightarrow D_s^- \pi^+$ based on a data sample corresponding to 0.37 fb$^{-1}$ of proton-proton collisions at $\sqrt{s} = 7$ TeV collected in 2011 with the LHCb detector. In addition, the ratio of B meson production fractions $f_s/f_d$, determined from semileptonic decays, together with the known branching fraction of the control channel $B^0 \rightarrow D^- \pi^+$, is used to perform an absolute measurement of the branching fractions:

$$B \left( B^0_s \rightarrow D_s^- \pi^+ \right) = \left( 2.95 \pm 0.05 \pm 0.17\,^{+0.18}_{-0.22} \right) \times 10^{-3},$$
$$B \left( B^0_s \rightarrow D_s^{\mp} K^\pm \right) = \left( 1.90 \pm 0.12 \pm 0.13\,^{+0.12}_{-0.14} \right) \times 10^{-4},$$

where the first uncertainty is statistical, the second the experimental systematic uncertainty, and the third the uncertainty due to $f_s/f_d$.

1 Introduction

Unlike the flavour-specific decay $B^0_s \rightarrow D_s^- \pi^+$, the Cabibbo-suppressed decay $B^0_s \rightarrow D_s^\mp K^\pm$ proceeds through two different tree-level amplitudes of similar strength: a $\bar{b} \rightarrow \bar{c}u\bar{s}$ transition leading to $B^0_s \rightarrow D_s^- K^+$ and a $\bar{b} \rightarrow \bar{u}c\bar{s}$ transition leading to $B^0_s \rightarrow D_s^+ K^-$. These two decay amplitudes can have a large $CP$-violating interference via $B^0_s - \bar{B}^0_s$ mixing, allowing the determination of the CKM angle $\gamma$ with negligible theoretical uncertainties through the measurement of tagged and untagged time-dependent decay rates to both the $D_s^- K^+$ and $D_s^+ K^-$ final states [1]. Although the $B^0_s \rightarrow D_s^\mp K^\pm$ decay mode has been observed by the CDF [2] and Belle [3] collaborations, only the LHCb experiment has both the necessary decay time resolution and access to large enough signal yields to perform the time-dependent $CP$ measurement. In this analysis, the $B^0_s \rightarrow D_s^\mp K^\pm$ branching fraction is determined relative to $B^0_s \rightarrow D_s^- \pi^+$, and the absolute $B^0_s \rightarrow D_s^- \pi^+$ branching fraction is determined using the known branching fraction of $B^0 \rightarrow D^- \pi^+$ and the production fraction ratio between the strange and up/down $B$ meson species, $f_s/f_d$ [4]. The two measurements are then combined to obtain the absolute branching fraction of the decay $B^0_s \rightarrow D_s^\mp K^\pm$. In addition to their intrinsic value, these measurements are necessary milestones on the road to $\gamma$ as they imply a good understanding of the mass spectrum and consequently of the backgrounds. Charge conjugate modes are implied throughout. Our notation $B^0 \rightarrow D^- \pi^+$, which matches that of ref. [5], encompasses both the Cabibbo-favoured $B^0 \rightarrow D^- \pi^+$ mode and the doubly-Cabibbo-suppressed $B^0 \rightarrow D^+ \pi^-$ mode.

The LHCb detector [6] is a single-arm forward spectrometer covering the pseudo-rapidity range $2 < \eta < 5$, designed for studying particles containing $b$ or $c$ quarks. In what follows “transverse” means transverse to the beamline. The detector includes a high-precision tracking system consisting of a silicon-strip vertex detector surrounding the $pp$
interaction region, a large-area silicon-strip detector located upstream of a dipole magnet with a bending power of about 4 Tm, and three stations of silicon-strip detectors and straw drift tubes placed downstream. The combined tracking system has a momentum resolution $\Delta p/p$ that varies from 0.4% at 5 GeV/$c$ to 0.6% at 100 GeV/$c$, an impact parameter resolution of 20 $\mu$m for tracks with high transverse momentum, and a decay time resolution of 50 fs. Impact parameter is defined as the transverse distance of closest approach between the track and a primary interaction. Charged hadrons are identified using two ring-imaging Cherenkov detectors. Photon, electron and hadron candidates are identified by a calorimeter system consisting of scintillating-pad and pre-shower detectors, an electromagnetic calorimeter, and a hadronic calorimeter. Muons are identified by a muon system composed of alternating layers of iron and multiwire proportional chambers.

The LHCb trigger consists of a hardware stage, based on information from the calorimeter and muon systems, followed by a software stage which applies a full event reconstruction. Two categories of events are recognised based on the hardware trigger decision. The first category are events triggered by tracks from candidate signal decays which have an associated cluster in the hadronic calorimeter. The second category are events triggered independently of the particles associated with the candidate signal decay by either the muon or calorimeter triggers. This selection ensures that tracks from the candidate signal decay are not associated to muon segments or clusters in the electromagnetic calorimeter and suppresses backgrounds from semileptonic decays. Events which do not fall into either of these two categories are not used in the subsequent analysis. The second, software, trigger stage requires a two-, three- or four-track secondary vertex with a large value of the scalar sum of the transverse momenta ($p_T$) of the tracks, and a significant displacement from the primary interaction. At least one of the tracks used to form this vertex is required to have $p_T > 1.7$ GeV/$c$, an impact parameter $\chi^2 > 16$, and a track fit $\chi^2$/ndf < 2. A multivariate algorithm is used for the identification of the secondary vertices [7]. Each input variable is binned to minimise the effect of systematic differences between the trigger behaviour on data and simulated events.

The samples of simulated events used in this analysis are based on the Pythia 6.4 generator [8], with a choice of parameters specifically configured for LHCb [9]. The EvtGen package [10] describes the decay of the $B$ mesons, and the Geant4 package [11] simulates the detector response. QED radiative corrections are generated with the Photos package [12].

The analysis is based on a sample of $pp$ collisions corresponding to an integrated luminosity of 0.37 fb$^{-1}$, collected at the LHC in 2011 at a centre-of-mass energy $\sqrt{s} = 7$ TeV. In what follows, signal significance will mean $S/\sqrt{S+B}$.

2 Topological selection

The decay modes $B_s^0 \rightarrow D_s^- \pi^+$ and $B_s^0 \rightarrow D_s^+ K^-$ are topologically identical and are selected using identical geometric and kinematic criteria, thereby minimising efficiency corrections in the ratio of branching fractions. The decay mode $B^0 \rightarrow D^- \pi^+$ has a similar topology to the other two, differing only in the Dalitz plot structure of the $D$ decay and the lifetime of
the $D$ meson. These differences are verified, using simulated events, to alter the selection efficiency at the level of a few percent, and are taken into account.

The $B^0_s (B^0)$ candidates are reconstructed from a $D^-_s (D^-)$ candidate and an additional pion or kaon (the “bachelor” particle), with the $D^-_s (D^-)$ meson decaying in the $K^+ K^- \pi^- (K^+ \pi^- \pi^-)$ mode. No requirements are applied on the $K^+ K^-$ or the $K^+ \pi^- \pi^-$ invariant masses. A mass constraint on the $D$ meson, selected with a tight mass window of 1948-1990 MeV, is applied when computing the $B$ meson mass.

All selection criteria will now be specified for the $B^0_s$ decays, and are implied to be identical for the $B^0$ decay unless explicitly stated otherwise. All final-state particles are required to satisfy a track fit $\chi^2/\text{ndf} < 4$ and to have a high transverse momentum and a large impact parameter $\chi^2$ with respect to all primary vertices in the event. In order to remove backgrounds which contain the same final-state particles as the signal decay, and therefore have the same mass lineshape, but do not proceed through the decay of a charmed meson, the flight distance $\chi^2$ of the $D^-_s$ from the $B^0_s$ is required to be larger than 2. Only $D^-_s$ and bachelor candidates forming a vertex with a $\chi^2/\text{ndf} < 9$ are considered as $B^0_s$ candidates. The same vertex quality criterion is applied to the $D^-_s$ candidates. The $B^0_s$ candidate is further required to point to the primary vertex imposing $\theta_{\text{flight}} < 0.8$ degrees, where $\theta_{\text{flight}}$ is the angle between the candidate momentum vector and the line between the primary vertex and the $B^0_s$ vertex. The $B^0_s$ candidates are also required to have a $\chi^2$ of their impact parameter with respect to the primary vertex less than 16.

Further suppression of combinatorial backgrounds is achieved using a gradient boosted decision tree technique\cite{13} identical to the decision tree used in the previously published determination of $f_s/f_d$ with the hadronic decays\cite{14}. The optimal working point is evaluated directly from a sub-sample of $B^0_s \rightarrow D^-_s \pi^+$ events, corresponding to 10% of the full dataset used, distributed evenly over the data taking period and selected using particle identification and trigger requirements. The chosen figure of merit is the significance of the $B^0_s \rightarrow D^-_s K^+$ signal, scaled according to the Cabibbo suppression relative to the $B^0_s \rightarrow D^-_s \pi^+$ signal, with respect to the combinatorial background. The significance exhibits a wide plateau around its maximum, and the optimal working point is chosen at the point in the plateau which maximizes the signal yield. Multiple candidates occur in about 2% of the events and in such cases a single candidate is selected at random.

### 3 Particle identification

Particle identification (PID) criteria serve two purposes in the selection of the three signal decays $B^0 \rightarrow D^- \pi^+$, $B^0_s \rightarrow D^-_s \pi^+$ and $B^0_s \rightarrow D^-_s K^\pm$. When applied to the decay products of the $D^-_s$ or $D^-$, they suppress misidentified backgrounds which have the same bachelor particle as the signal mode under consideration, henceforth the “cross-feed” backgrounds. When applied to the bachelor particle (pion or kaon) they separate the Cabibbo-favoured from the Cabibbo-suppressed decay modes. All PID criteria are based on the differences in log-likelihood (DLL) between the kaon, proton, or pion hypotheses. Their efficiencies are obtained from calibration samples of $D^{*+} \rightarrow (D^0 \rightarrow K^- \pi^+) \pi^+$ and $\Lambda \rightarrow p \pi^-$ signals, which are themselves selected without any PID requirements. These samples are split
sample requires the suppression of the $D^0$ mass hypothesis, lies within the data sample and the $D_s^-$ decay $B^0 \rightarrow D_s^- \pi^+$.

The selection of a pure $B^0 \rightarrow D^- \pi^+$ sample can be accomplished with minimal PID requirements since all cross-feed backgrounds are less abundant than the signal. The $\Lambda_b^0 \rightarrow \Lambda_c^- \pi^+$ background is suppressed by requiring that both pions produced in the $D^-$ decay satisfy $\mathrm{DLL}_{\pi^-} > -10$, and the $B^0 \rightarrow D^- K^+$ background is suppressed by requiring that the bachelor pion satisfies $\mathrm{DLL}_{K^-} < 0$.

The selection of a pure $B_s^0 \rightarrow D_s^- \pi^+$ or $B_s^0 \rightarrow D_s^+ K^\mp$ sample requires the suppression of the $B^0 \rightarrow D^- \pi^+$ and $\Lambda_b^0 \rightarrow \Lambda_c^- \pi^+$ backgrounds, whereas the combinatorial background contributes to a lesser extent. The $D^-$ contamination in the $D_s^-$ data sample is reduced by requiring that the kaon which has the same charge as the pion in $D_s^- \rightarrow K^+ K^- \pi^-$ satisfies $\mathrm{DLL}_{K^-} > 5$. In addition, the other kaon is required to satisfy $\mathrm{DLL}_{K^-} > 0$.

This helps to suppress combinatorial as well as doubly misidentified backgrounds. For the same reason, the pion is required to have $\mathrm{DLL}_{K^-} < 5$. The contamination of $\Lambda_b^0 \rightarrow \Lambda_c^- \pi^+$, $\Lambda_c^- \rightarrow \bar{p} K^+ \pi^-$ is reduced by applying a requirement of $\mathrm{DLL}_{K^-} > 0$ to the candidates that, when reconstructed under the $\Lambda_c^- \rightarrow \bar{p} K^+ \pi^-$ mass hypothesis, lie within $\pm 21 \text{ MeV}/c^2$ of the $\Lambda_c^-$ mass.

Because of its larger branching fraction, $B_s^0 \rightarrow D_s^- \pi^+$ is a significant background to $B_s^0 \rightarrow D_s^+ K^\mp$. It is suppressed by demanding that the bachelor satisfies the criterion $\mathrm{DLL}_{K^-} > 5$. Conversely, a sample of $B_s^0 \rightarrow D_s^- \pi^+$, free of $B_s^0 \rightarrow D_s^+ K^\mp$ contamination, is obtained by requiring that the bachelor satisfies $\mathrm{DLL}_{K^-} < 0$. The efficiency and misidentification probabilities for the PID criterion used to select the bachelor, $D^-$, and $D_s^-$ candidates are summarised in table 1.

Table 1. PID efficiency and misidentification probabilities, separated according to the up (U) and down (D) magnet polarities. The first two lines refer to the bachelor track selection, the third line is the $D^-$ efficiency and the fourth the $D_s^-$ efficiency. Probabilities are obtained from the efficiencies in the $D^{*+}$ calibration sample, binned in momentum and $p_T$. Only bachelor tracks with momentum below 100 GeV/c are considered. The uncertainties shown are the statistical uncertainties due to the finite number of signal events in the PID calibration samples.

4 Mass fits

The fits to the invariant mass distributions of the $B_s^0 \rightarrow D_s^- \pi^+$ and $B_s^0 \rightarrow D_s^+ K^\mp$ candidates require knowledge of the signal and background shapes. The signal lineshape is taken from a fit to simulated signal events which had the full trigger, reconstruction, and selection chain applied to them. Various lineshape parameterisations have been examined. The best fit to
the simulated event distributions is obtained with the sum of two Crystal Ball functions [15] with a common peak position and width, and opposite side power-law tails. Mass shifts in the signal peaks relative to world average values [5], arising from an imperfect detector alignment [16], are observed in the data. These are accounted for in all lineshapes which are taken from simulated events by applying a shift of the relevant size to the simulation. A constraint on the $D_s^-$ meson mass is used to improve the $B_s^0$ mass resolution. Three kinds of backgrounds need to be considered: fully reconstructed (misidentified) backgrounds, partially reconstructed backgrounds with or without misidentification (e.g. $B^0_\pi \rightarrow D^*_s-K^+$ or $B^0_s \rightarrow D^-\rho^+$), and combinatorial backgrounds.

The three most important fully reconstructed backgrounds are $B^0 \rightarrow D^-sK^+$ and $B^0 \rightarrow D^-s\pi^+$ for $B^0_\pi \rightarrow D^*_sK^+$, and $B^0 \rightarrow D^-\pi^+$ for $B^0_\pi \rightarrow D^-\pi^+$. The mass distribution of the $B^0 \rightarrow D^-\pi^+$ events does not suffer from fully reconstructed backgrounds. In the case of the $B^0 \rightarrow D^-sK^+$ decay, which is fully reconstructed under its own mass hypothesis, the signal shape is fixed to be the same as for $B^0_\pi \rightarrow D^*_sK^+$ and the peak position is fixed to that found for the signal in the $B^0 \rightarrow D^-\pi^+$ fit. The shapes of the misidentified backgrounds $B^0 \rightarrow D^-\pi^+$ and $B^0_\pi \rightarrow D^-\pi^+$ are taken from data using a reweighting procedure. First, a clean signal sample of $B^0 \rightarrow D^-\pi^+$ and $B^0_\pi \rightarrow D^-\pi^+$ decays is obtained by applying the PID selection for the bachelor track given in section 3. The invariant mass of these decays under the wrong mass hypothesis ($B^0_\pi \rightarrow D^-\pi^+$ or $B^0_\pi \rightarrow D^*_sK^+$) depends on the momentum of the misidentified particle. This momentum distribution must therefore be reweighted by taking into account the momentum dependence of the misidentification rate. This dependence is obtained using a dedicated calibration sample of $D^{*+}$ decays originating from primary interactions. The mass distributions under the wrong mass hypothesis are then reweighted using this momentum distribution to obtain the $B^0 \rightarrow D^-\pi^+$ and $B^0_\pi \rightarrow D^-\pi^+$ mass shapes under the $B^0_\pi \rightarrow D^-\pi^+$ and $B^0_\pi \rightarrow D^*_sK^+$ mass hypotheses, respectively.

For partially reconstructed backgrounds, the probability density functions (PDFs) of the invariant mass distributions are taken from samples of simulated events generated in specific exclusive modes and are corrected for mass shifts, momentum spectra, and PID efficiencies in data. The use of simulated events is justified by the observed good agreement between data and simulation.

The combinatorial background in the $B^0_\pi \rightarrow D^-s\pi^+$ and $B^0 \rightarrow D^-\pi^+$ fits is modelled by an exponential function where the exponent is allowed to vary in the fit. The resulting shape and normalisation of the combinatorial backgrounds are in agreement within one standard deviation with the distribution of a wrong-sign control sample (where the $D_s^-$ and the bachelor track have the same charges). The shape of the combinatorial background in the $B^0_s \rightarrow D^*_sK^+$ fit cannot be left free because of the partially reconstructed backgrounds which dominate in the mass region below the signal peak. In this case, therefore, the combinatorial slope is fixed to be flat, as measured from the wrong sign events.

In the $B^0_\pi \rightarrow D^*_sK^+$ fit, an additional complication arises due to backgrounds from $A^0_\pi \rightarrow D^-\bar{p}$ and $A^0_s \rightarrow D^*_s\bar{p}$, which fall in the signal region when misreconstructed. To avoid a loss of $B^0_\pi \rightarrow D^*_sK^+$ signal, no requirement is made on the DLL$_{K^-\bar{p}}$ of the bachelor particle. Instead, the $A^0_\pi \rightarrow D^-\bar{p}$ mass shape is obtained from simulated $A^0_\pi \rightarrow D^-\bar{p}$ decays,
which are reweighted in momentum using the efficiency of the DLL\(_{K}\rightarrow\pi\rightarrow\pi\) > 5 requirement on protons. The \(\bar{B}\_s^0 \rightarrow D_s^- \pi^+\) mass shape is obtained by shifting the \(\bar{B}\_b^0 \rightarrow D_s^- \pi^+\) mass shape downwards by 200 MeV/c\(^2\). The branching fractions of \(\bar{B}\_b^0 \rightarrow D_s^- \pi^+\) and \(\bar{B}\_b^0 \rightarrow D_s^- \pi^+\) are assumed to be equal, motivated by the fact that the decays \(B^0 \rightarrow D^- D_s^+\) and \(B^0 \rightarrow D^- D_s^+\) (dominated by similar tree topologies) have almost equal branching fractions. Therefore the overall mass shape is formed by summing the \(\bar{B}\_b^0 \rightarrow D_s^- \pi^+\) and \(\bar{B}\_b^0 \rightarrow D_s^- \pi^+\) shapes with equal weight; this assumption is tested as part of the study of systematic uncertainties and is not found to contribute significantly to them.

The signal yields are obtained from unbinned extended maximum likelihood fits to the data. In order to achieve the highest sensitivity, the sample is separated according to the two magnet polarities, allowing for possible differences in PID performance and in running conditions. A simultaneous fit to the samples collected with the two magnet polarities is performed for each decay, with the peak position and width of each signal, as well as the combinatorial background shape, shared between the two. The fitted signal yields in each polarity are independent of each other.

The fit under the \(B_s^0 \rightarrow D_s^- \pi^+\) hypothesis requires a description of the \(B^0 \rightarrow D^- \pi^+\) background. A fit to the \(B^0 \rightarrow D^- \pi^+\) spectrum is first performed to determine the yield of signal \(B^0 \rightarrow D^- \pi^+\) events, shown in figure 1. The expected \(B^0 \rightarrow D^- \pi^+\) contribution under the \(B_s^0 \rightarrow D_s^- \pi^+\) hypothesis is subsequently constrained with a 10% uncertainty to account for uncertainties on the PID efficiencies. The fits to the \(B_s^0 \rightarrow D_s^- \pi^+\) candidates are shown in figure 1 and the fit results for both decay modes are summarised in table 2. The peak position of the signal shape is varied, as are the yields of the different partially reconstructed backgrounds (except \(B^0 \rightarrow D^- \pi^+\)) and the shape of the combinatorial background. The width of the signal is fixed to the values found in the \(B^0 \rightarrow D^- \pi^+\) fit (17.2 MeV/c\(^2\)), scaled by the ratio of widths observed in simulated events between \(B^0 \rightarrow D^- \pi^+\) and \(B_s^0 \rightarrow D_s^- \pi^+\) decays (0.987). The accuracy of these fixed parameters is evaluated using ensembles of simulated experiments described in section 5. The yield of \(B^0 \rightarrow D^- \pi^+\) is fixed to be 2.9% of the \(B_s^0 \rightarrow D_s^- \pi^+\) signal yield, based on the world average branching fraction of \(B^0 \rightarrow D_s^- \pi^+\) of \((2.16 \pm 0.26) \times 10^{-5}\), the value of \(f_s/f_d\) given in [4], and the value of the branching fraction computed in this paper. The shape used to fit this component is the sum of two Crystal Ball functions obtained from the \(B_s^0 \rightarrow D_s^- \pi^+\) sample with the peak position fixed to the value obtained with the fit of the \(B^0 \rightarrow D^- \pi^+\) data sample and the width fixed to the width of the \(B_s^0 \rightarrow D_s^- \pi^+\) peak.

The \(\bar{B}\_b^0 \rightarrow \bar{B}\_c^0 \pi^+\) background is negligible in this fit owing to the effectiveness of the veto procedure described earlier. Nevertheless, a \(\bar{B}\_b^0 \rightarrow \bar{B}\_c^0 \pi^+\) component, whose yield is allowed to vary, is included in the fit (with the mass shape obtained using the reweighting procedure on simulated events described previously) and results in a negligible contribution, as expected.

The fits for the \(B_s^0 \rightarrow D_s^+ K^+\) candidates are shown in figure 2 and the fit results are collected in table 2. There are numerous reflections which contribute to the mass distribution. The most important reflection is \(B_s^0 \rightarrow D_s^- \pi^+\), whose shape is taken from the earlier \(B_s^0 \rightarrow D_s^- \pi^+\) signal fit, reweighted according to the efficiencies of the applied PID requirements. Furthermore, the yield of the \(B^0 \rightarrow D^- K^+\) reflection is constrained to the values in table 3. In addition, there is potential cross-feed from partially reconstructed modes with a
misidentified pion such as $B^0_s \rightarrow D^- \rho^+$, as well as several small contributions from partially reconstructed backgrounds with similar mass shapes. The yields of these modes, whose branching fractions are known or can be estimated (e.g. $B^0_s \rightarrow D^- \rho^+$, $B^0_s \rightarrow D^- K^{*+}$), are constrained to the values in table 3, based on criteria such as relative branching fractions and reconstruction efficiencies and PID probabilities. An important cross-check is performed by comparing the fitted value of the yield of misidentified $B^0_s \rightarrow D^- \pi^+$ events ($318 \pm 30$) to the yield expected from PID efficiencies ($370 \pm 11$) and an agreement is found.

Table 2. Results of the mass fits to the \(B^0 \to D^- \pi^+, B_s^0 \to D_s^- \pi^+, \) and \(B_s^0 \to D_s^{+}/D_s^{\mp} K^\pm\) candidates separated according to the up (U) and down (D) magnet polarities. In the \(B_s^0 \to D_s^{+}/D_s^{\mp} K^\pm\) case, the number quoted for \(B_s^0 \to D_s^- \pi^+\) also includes a small number of \(B^0 \to D^- \pi^+\) events which have the same mass shape (20 events from the expected misidentification). See table 3 for the constrained values used in the \(B_s^0 \to D_s^{+}/D_s^{\mp} K^\pm\) decay fit for the partially reconstructed backgrounds and the \(B^0 \to D^- K^\pm\) decay channel.

### Figure 2.

Mass distribution of the \(B_s^0 \to D_s^{+}/D_s^{\mp} K^\pm\) candidates. The stacked background shapes follow the same top-to-bottom order in the legend and the plot. For illustration purposes the plot includes events from both magnet polarities, but they are fitted separately as described in the text.

### 5 Systematic uncertainties

The major systematic uncertainties on the measurement of the relative branching fraction of \(B_s^0 \to D_s^{+}/D_s^{\mp} K^\pm\) and \(B^0 \to D^- \pi^+\) are related to the fit, PID calibration, and trigger and offline selection efficiency corrections. Systematic uncertainties related to the fit are

evaluated by generating large sets of simulated experiments. During generation, certain parameters are varied. The samples are fitted with the nominal model. To give two examples, during generation the signal width is fixed to a value different from the width used in the nominal model, or the combinatorial background slope in the \(B_{s}^{0} \to D_{s}^{\mp} K_{\pm}\) fit is fixed to the combinatorial background slope found in the \(B_{s}^{0} \to D_{s}^{-} \pi^{\pm}\) fit. The deviations of the peak position of the pull distributions from zero are then included in the systematic uncertainty.

In the case of the \(B_{s}^{0} \to D_{s}^{\mp} K_{\pm}\) fit the presence of constraints for the partially reconstructed backgrounds must be considered. The generic extended likelihood function can be written as

\[
\mathcal{L} = \frac{e^{-N} N^{N_{\text{obs}}}}{N_{\text{obs}}!} \times \prod_{j} G(N_{j}; N_{j}^{0}, \sigma_{N_{j}^{0}}) \times \prod_{i=1}^{N_{\text{obs}}} P(m_{i}; \vec{\lambda}),
\]

where the first factor is the extended Poissonian likelihood in which \(N\) is the total number of fitted events, given by the sum of the fitted component yields \(N = \sum_{k} N_{k}\). The fitted data sample contains \(N_{\text{obs}}\) events. The second factor is the product of the \(j\) external constraints on the yields, \(j < k\), where \(G\) stands for a Gaussian PDF, and \(N_{j}^{0} \pm \sigma_{N_{j}^{0}}\) is the constraint value. The third factor is a product over all events in the sample, \(P\) is the total PDF of the fit, \(P(m_{i}; \vec{\lambda}) = \sum_{k} N_{k} P_{k}(m_{i}; \vec{\lambda}_{k})\), and \(\vec{\lambda}\) is the vector of parameters that define the mass shape and are not fixed in the fit.
Each simulated dataset is generated by first varying the component yield \(N_k\) using a Poissonian PDF, then sampling the resulting number of events from \(P_k\), and repeating the procedure for all components. In addition, constraint values \(N^0_c\) used when fitting the simulated dataset are generated by drawing from \(G(N; N^0_c, \sigma^0_N)\), where \(N^0_c\) is the true central value of the constraint, while in the nominal fit to the data \(N^0_c = N^0\).

The sources of systematic uncertainty considered for the fit are signal widths, the slope of the combinatorial backgrounds, and constraints placed on specific backgrounds. The largest deviations are due to the signal widths and the fixed slope of the combinatorial background in the \(B^0_s \to D^+_s K^\pm\) fit.

The systematic uncertainty related to PID enters in two ways: firstly as an uncertainty on the overall efficiencies and misidentification probabilities, and secondly from the shape for the misidentified backgrounds which relies on correct reweighting of PID efficiency versus momentum. The absolute errors on the individual \(K\) and \(\pi\) efficiencies, after reweighting of the \(D^*^+\) calibration sample, have been determined for the momentum spectra that are relevant for this analysis, and are found to be 0.5% for DLL\(K^-\pi<0\) and 0.5% for DLL\(K^-\pi>5\).

The observed signal yields are corrected by the difference observed in the (non-PID) selection efficiencies of different modes as measured from simulated events:

\[
\frac{\epsilon_{\text{Sel}B^0_s \to D^-_s \pi^+}}{\epsilon_{\text{Sel}B^0_s \to D^-_s \pi^+}} = 1.020 \pm 0.016 , \\
\frac{\epsilon_{\text{Sel}B^0_s \to D^+_s K^\pm}}{\epsilon_{\text{Sel}B^0_s \to D^+_s K^\pm}} = 1.061 \pm 0.016 .
\]

A systematic uncertainty is assigned on the ratio to account for percent level differences between the data and the simulation. These are dominated by the simulation of the hardware trigger. All sources of systematic uncertainty are summarized in table 4.

### 6 Determination of the branching fractions

The \(B^0_s \to D^+_s K^\pm\) branching fraction relative to \(B^0_s \to D^-_s \pi^+\) is obtained by correcting the raw signal yields for PID and selection efficiency differences

\[
\frac{B(B^0_s \to D^+_s K^\pm)}{B(B^0_s \to D^-_s \pi^+)} = \frac{N_{B^0_s \to D^+_s K^\pm}}{N_{B^0_s \to D^-_s \pi^+}} \frac{\epsilon_{\text{PID}B^0_s \to D^-_s \pi^+}}{\epsilon_{\text{PID}B^0_s \to D^-_s \pi^+}} \frac{\epsilon_{\text{Sel}B^0_s \to D^-_s \pi^+}}{\epsilon_{\text{Sel}B^0_s \to D^-_s \pi^+}} ,
\]

where \(\epsilon_X\) is the efficiency to reconstruct decay mode \(X\) and \(N_X\) is the number of observed events in this decay mode. The PID efficiencies are given in table 1, and the ratio of the two selection efficiencies were given in the previous section.

The ratio of the branching fractions of \(B^0_s \to D^+_s K^\pm\) relative to \(B^0_s \to D^-_s \pi^+\) is determined separately for the down (0.0601±0.0056) and up (0.0694±0.0066) magnet polarities and the two results are in good agreement. The quoted errors are purely statistical. The combined result is

\[
\frac{B(B^0_s \to D^+_s K^\pm)}{B(B^0_s \to D^-_s \pi^+)} = 0.0646 \pm 0.0043 \pm 0.0025 ,
\]
where the first uncertainty is statistical and the second is the total systematic uncertainty from table 4.

The relative yields of $B^0_s \to D^- \pi^+$ and $B^0 \to D^- \pi^+$ are used to extract the branching fraction of $B^0_s \to D^- \pi^+$ from the following relation

$$\frac{\mathcal{B}(B^0_s \to D^- \pi^+)}{\mathcal{B}(B^0 \to D^- \pi^+)} = \frac{\epsilon_{\text{Sel}}^{B^0_s \to D^- \pi^+} \epsilon_{\text{PID}}^{B^0 \to D^- \pi^+}}{\epsilon_{\text{Sel}}^{B^0 \to D^- \pi^+} \epsilon_{\text{PID}}^{B^0_s \to D^- \pi^+}} \frac{N_{B^0_s \to D^- \pi^+}}{N_{B^0 \to D^- \pi^+}} \frac{B(D^- \to K^+ \pi^- \pi^-)}{B(D_s^- \to K^+ K^- \pi^-)}, \quad (6.2)$$

using the recent $f_s/f_d$ measurement from semileptonic decays [4]

$$f_s/f_d = 0.268 \pm 0.008^{+0.022}_{-0.020},$$

where the first uncertainty is statistical and the second systematic. Only the semileptonic result is used since the hadronic determination of $f_s/f_d$ relies on theoretical assumptions about the ratio of the branching fractions of the $B^0_s \to D^- \pi^+$ and $B^0 \to D^- \pi^+$ decays. In addition, the following world average values [5] for the $B$ and $D$ branching fractions are used

$$\mathcal{B}(B^0 \to D^- \pi^+) = (2.68 \pm 0.13) \times 10^{-3},$$
$$\mathcal{B}(D^- \to K^+ \pi^- \pi^-) = (9.13 \pm 0.19) \times 10^{-2},$$
$$\mathcal{B}(D_s^- \to K^+ K^- \pi^-) = (5.49 \pm 0.27) \times 10^{-2},$$

leading to

$$\mathcal{B}(B^0_s \to D^- \pi^+) = (2.95 \pm 0.05 \pm 0.17^{+0.18}_{-0.22}) \times 10^{-3},$$
$$\mathcal{B}(B^0_s \to D_s^+ K^+) = (1.90 \pm 0.12 \pm 0.13^{+0.12}_{-0.14}) \times 10^{-4},$$

where the first uncertainty is statistical, the second is the experimental systematics (as listed in table 4) plus the uncertainty arising from the $B^0 \to D^- \pi^+$ branching fraction, and the third is the uncertainty (statistical and systematic) from the semileptonic $f_s/f_d$ measurement. Both measurements are significantly more precise than the existing world averages [5].

**Acknowledgments**

We express our gratitude to our colleagues in the CERN accelerator departments for the excellent performance of the LHC. We thank the technical and administrative staff at CERN and at the LHCb institutes, and acknowledge support from the National Agencies: CAPES, CNPq, FAPERJ and FINEP (Brazil); CERN; NSFC (China); CNRS/IN2P3 (France); BMBF, DFG, HGF and MPG (Germany); SFI (Ireland); INFN (Italy); FOM and NWO (The Netherlands); SCSR (Poland); ANCS (Romania); MinES of Russia and Rosatom (Russia); MICINN, XuntaGal and GENCAT (Spain); SNSF and SER (Switzerland); NAS Ukraine (Ukraine); STFC (United Kingdom); NSF (USA).
