CDK1 links to RARγ in treatment response of cancer cells

Niels Ødum; Department of International Health, Immunology and Microbiology; Copenhagen University; Copenhagen, Denmark; Email: ndum@sund.ku.dk; http://dx.doi.org/10.4161/cc.25069

Cancer recurrence is associated with treatment failure and is the main cause of death, and thus remains a major clinical challenge. Elevated level of the cyclin-dependent kinase 1 (CDK1) correlates with cancer recurrence and treatment resistance in patients with breast cancer or colorectal cancer. It is proposed that defects in CDKs may lead to the accumulated genetic defects, which render cells less sensitive to drug-induced growth inhibition and apoptosis. CDK1 is the most essential CDK, as it alone is sufficient to drive cell division cycle in mammalian cells. CDK1 in complex with B-type cyclins regulates the mitotic entry of the cell cycle. Once DNA damages occur, CDK1/cyclin B1 becomes inactivated, and cells are prevented from entering mitosis until the damages are repaired. CDK1 is inactivated by the nuclear vs. cytoplasmic kinases Wee1 and Myt1, which phosphorylate CDK1 on its tyrosin-14 and -15 sites. While it is activated by the antagonist of Wee1 and Myt1, a family of phosphatases of Cdc25A, B and C dephosphorylate CDK1 on the same tyrosin-sites served for Wee1 and Myt1. The proper level and activity of CDK1 is thus kept in balance by these kinases and phosphatases that are involved in the cell cycle progression (Fig. 1). However, the role of CDK1 and the regulation of its phosphorylation and subcellular localization upon cellular response to chemotherapeutic drugs are poorly understood.

In a recent issue of Cell Cycle, Hedblom et al. showed that altered level of CDK1 is associated with disease recurrence and poor overall survival of patients with acute myeloid leukemia. These novel findings indicate that CDK1 is a critical factor mediating cellular response to ATRA treatment. Only elimination of CDK1, not CDK2, causes a decreased proportion of G0/G1 cells and a concomitant increase in mitotic cells, suggesting that cells without proper level of CDK1 had accelerated mitosis. Defects in CDK1 expression level thus confer U-937 leukemic cells to be less sensitive to all trans retinoic acid (ATRA)-induced G0/G1 cell cycle arrest and differentiation. Hedblom et al. demonstrate that defects in CDK1 expression cause alterations in the expression levels and activities of several proteins, which are the key regulators for cell growth and survival. These include: (1) elimination of CDK1 in U-937 cells leads to a significant reduction in the level of P27Kip, a key regulator for G0/G1 checkpoint; (2) elimination of CDK1 in U-937 cells also results in an increased level of phosphorylated Akt, a key survival factor. These alterations are likely linked to the CDK1-mediated resistance to ATRA treatment.

Hedblom et al. have unravelled several novel mechanisms on how the phosphorylation and subcellular localization of CDK1 is regulated upon cellular response to ATRA. Thus, ATRA receptor RARγ, (not RARα) is required for the regulation of CDK1 expression, phosphorylation and protein stability upon induction of ATRA. RARγ regulates CDK1 level and activity through a direct formation of protein-protein complex in the nucleus of U-937 cells and F9 cells. In the absence of RARγ, ATRA is unable to downregulate CDK1 expression and phosphorylation. This suggests that RARγ is a critical factor to balance the CDK1 level and activity to ensure ATRA to achieve optimal effects on cancer cells. Similar to what is observed in U-937 cells with defects in CDK1 expression; tumor cells with defects in RARγ also display a reduced level of P27Kip. Thus, RARγ and CDK1 may form a reciprocal regulatory circuit and influence the function and level of P27Kip protein, and control the G0/G1 phases of cell cycle.

Figure 1. To regulate the proper entry of mitosis, CDK1 is inhibited by Wee1 which phosphorylate CDK1, while it is activated by the hormone receptor RARγ. The novel findings suggest that the regulation of CDK1 is cooperatively mediated by the cell cycle regulators Wee1 and CDK1 and the hormone receptor RARγ in response to ATRA treatment.

Retinoid-based therapies are increasingly being utilized to treat various types of cancers. ATRA represents a class of anticancer drug that can induce tumor cells to differentiate and restore their normal function. Because CDK1 is a downstream effect protein of multiple pathways, including Wee1, and Cdc25A and Cdc25C and RARγ, the proper regulation of its expression and activity is essential for sensitizing the cells to respond to treatment. The study by Hedblom et al. suggests that CDK1 and its associated regulators are the ideal targets for cancer therapy, and their novel
findings highlight the therapeutic potential using ATRA for targeting CDK1 and its associated proteins in cancer.

Progesterone and FOXO1 signaling: Harnessing cellular senescence for the treatment of ovarian cancer

Jan J. Brosens1,* and Eric W.-F. Lam2; 1Division of Reproductive Health; Clinical Sciences Research Laboratories; University Hospital; Warwick Medical School; Coventry, UK; 2Department of Surgery and Cancer; Imperial Centre for Translational and Experimental Medicine (ICTEM); Imperial College London; London, UK; *Email: J.J.Brosens@warwick.ac.uk; http://dx.doi.org/10.4161/cc.25070

Senescence is an inbuilt cellular response that leads to irreversible cell cycle arrest.1 It plays a critical role in both aging and tumor suppression. While first observed in culture, cellular senescence happens in vivo. Premature senescence can be triggered by various insults, such as oncogene activation, telomere erosion, irradiation, DNA damage, oxidative stress and toxins, which emphasize the importance of the senescence pathway in arresting growth of prospective cancer cells that have accumulated potentially harmful genetic mutations.1

In the May 1, 2013 issue of Cell Cycle, Diep and colleagues report that the progesterone receptor (PR) cooperates with the Forkhead transcription factor FOXO1 to trigger cellular senescence in ovarian cancer cells.2 The authors found that PR not only regulates FOXO1 expression, but also cooperates with this transcription factor to activate genes that encode senescence-associated cell cycle inhibitors, such as p15INK4b, p16INK4a, p21Cip1 and p27Kip1 (Fig. 1). Importantly, they show that this response is induced upon treatment of cells with a synthetic PR agonist, dependent on the B isoform of PR and attenuated upon FOXO1 knockdown. The inference is that progestins, compounds widely used for a variety of clinical indications, could also be valuable in the management of ovarian cancer, the most lethal of all gynecological malignancies.

However, the present study shows that PR- and FOXO1-positive ovarian cancer cells can be tricked into entering senescence in response to progestins. The role of FOXO proteins in cellular senescence is well documented.3 In keeping with the findings of Diep et al.,2 it has been shown previously that overexpression or activation of FOXO proteins through inhibition of the upstream phosphatidylinositol-3-kinase (PI3K)/AKT signaling cascade promotes senescence via induction of cell cycle inhibitors, such as p27Kip1. Intriguingly, the cellular senescence induced in this way appears to be independent of p53 and p16INK4a, molecules important for the maintenance of senescence-associated cell cycle arrest.3

The present study not only identifies the PR-FOXO1 axis as a potential therapeutic target in ovarian cancer, but also helps to explain why expression of PR is a prognostic marker for ovarian cancer associated with longer progression-free survival. Similarly, this study provides a mechanistic explanation for why pregnancy, which is associated with high circulating progesterone levels, and the use of progestin-containing oral contraceptives may suppress the growth of premalignant cells in the ovarian cortex, thus protecting against ovarian cancer.4 There are, however, major

![Figure 1. Progestin-dependent activation of the senescence pathway.](image-url)

Figure 1. Progestin-dependent activation of the senescence pathway. Cancer cells have increased capacity to proliferate. Cellular senescence can be triggered by various insults. Progesterone promote ovarian cancer cells to enter senescence through activation of the progesterone receptor (PR), which cooperates with FOXO1 to induce expression of senescence-associated cell cycle inhibitors, including FOXO1, p15INK4b, p16INK4a, p21Cip1 and p27Kip1.
obstacles that limit the clinical use of progestins in ovarian cancer. Foremost, ovarian cancer is a heterogeneous disease that consists of etiologically distinct tumors that share an anatomical site. Consequently, progestin sensitivity is likely restricted to certain historical types, such endometrioid and serous cancers. Further, PR as well as FOXO1 are frequently lost in ovarian cancer; the robustness of the senescence response in vivo has not yet been studied, and the contribution of putative non-genomic progestin receptors in modulating cellular responses to hormonal therapies remains poorly understood and controversial. Nevertheless, the observations of Diep and colleagues should help to define molecular markers that identify those tumors likely to be responsive to progestin treatment, alone or combined with a PI3K/AKT inhibitor.

Notably, PR and FOXO1 interactions have also been studied in normal and malignant endometrium. In fact, these two transcription factors are also putative determinants of the responsiveness of endometrial cancer cells to chemotherapy and progestin treatment. In the context of reproduction, the induction of FOXO1 and subsequent binding to PR triggers the differentiation of endometrial stromal cells into secretory decidual cells, a process that is indispensable for embryo implantation and the formation of a functional placenta. Few studies have as yet examined senescence in decidual cells, although there is evidence that deregulation of this process can cause preterm labor. Approximately 12.9 million babies are born too soon every year, and more than 1 million die each year as a direct consequence of prematurity. Thus, targeting the FOXO1-PR axis to modulate cellular senescence in the uterus or ovary may unlock hitherto unrecognized therapeutic options of immense clinical value.

Rb and chromatin remodeling in the maintenance of the post-mitotic state of neurons

Andrusiak et al. have now examined whether the role of pRb in enforcing the post-mitotic state depends on its capacity to recruit LXCXE domain-containing chromatin remodeling activities. They made use of inducible loss-of-function alleles of Rb in vivo and in vitro to prevent the emergence of compensatory effects that can occur with constitutive loss-of-function models. The authors show that while the acute deletion of Rb leads to de-repression of E2F-targeted cell cycle genes in cortical neurons, those genes remain silent when the only remaining allele of Rb codes for a protein unable to interact with LXCXE domain-containing proteins (Fig. 1). Moreover, they show that the complete elimination of Rb changes the chromatin from a state refractory to transcription (nucleosomes trimethylated on H3K9 and poorly acetylated) to one that is more conducive to gene expression. Finally, the authors demonstrate that E2F proteins are responsible for the change in chromatin structure after...
complete deletion of Rb: no change in chromatin structure takes place when E2F proteins are prevented from binding to their target genes, and cells remain in their post-mitotic state. This rescue experiment demonstrates that pRb keeps mitotically arrested neurons out of the cell cycle by blocking E2F-mediated transcriptional activation of cell cycle genes, rather than by recruiting LXCXE-containing chromatin remodeling complexes.

These findings inform us on the multiple roles played by pRb in regulating gene silencing. During senescence or after exposure to genotoxic stress, pRb may cooperate with LXCXE-containing proteins to block the expression of target genes and suppress tumorigenesis. However, permanent mitotic exit appears to rely on a different function of pRb: that of antagonizing E2F-mediated cell cycle gene activation.

References

Figure 1. LXCXE-independent chromatin remodeling and cell cycle repression in mitotically arrested cells. Andrusiak et al. reported that in cortical neurons of the adult brain, which have permanently ceased proliferation, the acute loss of pRb leads to chromatin remodeling at cell cycle genes, to cell cycle re-entry and to apoptotic loss of neurons. In contrast, loss of pRb’s ability to interact with LXCXE-containing proteins does not lead to changes in chromatin structure or to cell cycle re-entry. Moreover, the loss of pRb phenotype can be reversed if the action of E2F proteins is blocked by the overexpression of a dominant-negative form of DP1 that blocks E2F DNA binding.

Progestins: Pro-senescence therapy for ovarian cancer?
Steffi Oesterreich,1,2* Robert Edwards1,3 and Anda Vlad 1,3; 1Womens Cancer Research Center; University of Pittsburgh Cancer Institute and Magee-Womens Research Institute; University of Pittsburgh; Pittsburgh, PA USA; 2Department of Pharmacology and Chemical Biology; University of Pittsburgh; Pittsburgh, PA USA; 3Department of Obstetrics, Gynecology and Reproductive Sciences; University of Pittsburgh School of Medicine; Pittsburgh, PA USA; *Email: oesterreichs@upmc.edu; http://dx.doi.org/10.4161/cc.25072

Increasing epidemiological evidence suggests a role of steroid hormones in the development and progression of certain molecular subtypes of ovarian cancer. In general, the data suggest that estrogens are associated with increased risk of ovarian cancer, while progesterone and progestins may have a protective role (for recent review on this topic, see ref. 1). Despite these epidemiological associations, there remains a surprisingly limited understanding of the underlying biology and mechanisms of steroid receptor action in early and late stages of ovarian tumorigenesis. However, given that hormonal therapies represent the best of “targeted therapy in personalized medicine,” with limited toxicities, there is renewed interest in the static and maintenance roles for hormonal therapy in ovarian...
In the May 1, 2013 issue of *Cell Cycle*, Carol Lange and colleagues published an exciting study, which provides mechanistic insight into how progesterone receptor (PR) mediates the protective effects of progestins in ovarian cancer. The authors used a number of established ovarian cancer cell lines of different histological subtypes to show that progestins activate nuclear PR, leading to elevated FOXO1 expression and ultimately cellular senescence. Senescence is at least in part due to the induction of the cell cycle inhibitor p21. It is important to point out that in addition to the elegant mechanistic studies, the authors provide very valuable and extensive data on PR protein expression in the different molecular subtypes of human ovarian cancer, showing low PR expression in clear cell and mucinous tumors (3 and 18%, respectively) and moderate to high expression in serous (35%), low-grade serous (64%) and endometrioid tumors (67%) (Fig. 1).

As with other scientific studies, this manuscript provides clues to mechanism of action of progestins but at the same time raises many new questions. For example, what is the cause for the biphasic dose response to progestins? Does this imply a critical role for the other progesterone-binding proteins? And can this explain prior discrepant results showing both progesterone-induced apoptosis and proliferation? Importantly, given the increasing realization of diverse roles of the two PR isoforms, PR-A and PR-B, what can we expect to see from loss (or overexpression) of the PR-A isoform? And, finally, what is the role of PR action in the tumor microenvironment?

This study has important translational implications, in that PR agonists (and antagonists) are clinically available. However, to date, small clinical trial cohorts have demonstrated modest activity in ovarian cancer. Many of these trials have limitations, and it might be time to revisit the potential use of progestins and anti-progestins in ovarian cancer therapy. Several steps can be taken. First and foremost is the need to use biomarkers to predict active PR signaling in the tumor (and possibly the stroma). In addition, clinical trials mostly occurred in chemotherapy-resistant, late-stage disease; however, data at hand suggest that there is progressive loss of PR during tumor progression. This might imply a place for progestin in early-stage tumorigenesis, perhaps from precursors like endometriosis, which predispose to endometrioid, clear cell and low-grade serous ovarian tumors (Fig. 1).

In support of this rationale is the fact that PR expression is highest in low-grade serous and endometrioid (although not clear cell) tumors, further suggesting the early roles of PR-mediated pathogenesis and the potential for PR-targeted therapy or prevention, at least in some histological subtypes. And finally, the idea of using synthetic lethal approaches, i.e., combining progestin with drugs showing increased efficacy against senescent cells would be warranted. One approach that comes to mind is the use of immune therapies. Senescence of epithelial tumor cells leads to the release of inflammatory proteins and mediators of extracellular matrix (also called the senescent- messaging secretome or SMS), which can act as activators of the innate immune response, leading to tumor cell clearance. In addition, active immunization with senescent cell-derived, tumor antigen-based vaccines may act in synergy to the potentially immunogenic in vivo inducers of senescence (like progestins, for example), providing additional benefits in both therapeutic as well as preventive approaches, although the efficacy of such approaches remains to be determined.

In summary, a renewed effort to understand steroid hormone action in ovarian cancer (in both the epithelium and stroma) may lead to novel approaches for targeted therapies with limited toxicities and therapeutic benefit.

Escaping death to quiescence: Avoiding mitotic catastrophe after DNA damage

Zhiyuan Shen,* Steven C. Huhn and Bruce G. Haffty; The Cancer Institute of New Jersey; Department of Radiation Oncology; Robert Wood Johnson Medical School; New Brunswick, NJ USA; *Email: ashenzh@umdnj.edu; http://dx.doi.org/10.4161/cc.25073

When a mammalian cell exits G1 and enters the S-phase, it becomes committed to the completion of the entire cell cycle until the next G1 phase, where a quiescent status can be reached. However, when DNA damage is induced, mammalian cells may activate checkpoints that arrest the cell cycle during specific phases, such as G1, intra-S, and G2. The mechanisms dictating the exit from cycle arrest have major implications on cell fate and thus affect the outcome of DNA damage-based cancer therapies.

In one scenario, cells can recover from temporary arrest after DNA damage is repaired. This results in the resumption of cell cycle progression, although a fraction of the surviving cells may contain an altered genome due to mutagenic DNA repair. In another scenario, cells escape cycle arrest with residual DNA damage. This can lead to delayed cell death or genomic instability.1 Following release from G1 arrest, such events have the potential to induce cell death through mitotic catastrophe. Lastly, permanently arrested cells have the option to enter a quiescent G0/G1 status known as senescence. It is not difficult to see how long-term G1 arrest permits entrance into senescence, but it is unclear how G2-arrested cell can enter this state.

In a recent article, Ye et al. reported that the induction of long-term G2 arrest resulted in the complete omission of M-phase and facilitated the entrance into a tetraploid quiescent G2 phase. The investigators used a cell line that was previously shown to be able to undergo long-term G2 arrest after a high dose of ionizing radiation.3 They found that after 10 Gy of γ-irradiation, these cells underwent a long-term G2 arrest, which was never followed by mitosis. Critical genes involved in the G2-M transition were downregulated in the G2-arrested cells. Furthermore, these tetraploid quiescent cells displayed a senescent phenotype. This led to the conclusion that these G2-arrested cells directly bypassed mitosis and entered into a G1/G0 quiescent status. This is the first report that suggests G2 arrest induced by DNA damage can result in G2 slippage that bypasses mitosis, although it has been previously reported that long-term arrest at metaphase causes the abortion of mitosis (mitotic slippage) and subsequent entrance into G1.4

Unlike G1 phase, G2 phase is only a transient phase of the cell cycle. It is conceivable that if the damaged cells adapt to the long-term G2 arrest and prematurely enter mitosis with DNA damage, mitotic catastrophe is likely the outcome. Therefore, G2 slippage might be a mechanism for the cells to escape reproductive mitotic death to enter a quiescent status in the event of severe DNA damage at G1 or late S phase. The study by Ye et al. raises several questions relevant to radiation cancer therapy.

First, DNA damage induced senescence is considered to be a form of accelerated cellular senescence (ACS).3 The ACS cells retain some metabolic activities, but a small portion of the ACS cells may reenter the cell cycle.5 The senescent tetraploid G2 cells observed by Ye et al. were induced by a high dose of radiation and may be considered a form of ACS. It remains to be determined whether a small fraction of the tetraploid ACS cells formed after G2 slippage reentered the cell cycle, as this has significant implications for cancer therapy.

Second, a major mechanism of radiation induced proliferative cell death is through mitotic catastrophe. It was noted that the long-term G2 arrest and subsequent senescence by G2 slippage is more predominant at a high dose of irradiation than at a modest dose.2,3 This raises the interesting question of whether G2 slippage is a predominant outcome after high dose irradiation. The answer to this question would be relevant to the emerging concept of high dose stereotactic ablative radiotherapy.6,7 High doses could efficiently induce senescence that would quickly control tumor mass, but it would also enable cells to avoid cell death via mitotic catastrophe. Thus, ablative radiotherapy would be beneficial for the initial and local control of tumor mass, but it may also leave the possibility of tumor recurrence, because a small fraction of the therapy induced ACS cells may re-enter the cell cycle.3
