A Semantic Model For UNITY

Zhiming Liu*
University of Warwick

Abstract

This paper develops a semantic model for UNITY that reflects its particular aspects, such as *nondeterminism, absence of control flow* etc.. The proposed model is a kind of state-transition system within which *observations* and *actions* are the basic semantic objects. An alternative semantics for UNITY programs based on different fairness conditions is also defined using this model. Specially, the fairness condition assumed in [CM88] is defined and the UNITY logic based on it is modelled to show how the safety and liveness (progress) properties can be represented. This model is beeing used as the basis for developing some formal techniques for fault-tolerance within a UNITY framework.

1 Introduction

Much of program development consists of refining specifications by adding detail. Given a problem specification, we begin by proposing a general solution strategy. Usually the strategy is broad, admitting many solutions. Next we give a specification of the solution strategy and prove that this strategy (as specified) solves the problem (as specified). When we consider a specific set of target architectures, we may choose to narrow the solution strategy, which means refining the specification further. At each stage of refinement, the programmer is obliged to prove that the specification proposed indeed refines a specification proposed at earlier step. The construction of a program is begun only after the program has been specified in extensive detail. A framework has been developed in UNITY [CM88] to meet all these purposes.

UNITY can be taken as a theory – a computational model and an associated proof system in which programs can be viewed as **U**nbounded **N**ondeterministic **I**terative **T**ransformations. It based on the thesis that the unity of the programming task transcends differences between the architectures on which programs can be executed and the application domains from which problems are drawn. The goal of the UNITY work is to show how programs can be developed systematically for a variety of architectures and applications.

Programs can be developed for different architectures, e.g. the von Neumann architecture, synchronous shared-memory multiprocessors, and asynchronous shared-memory multiprocessors, through a series of refinements by specifying program execution with as little detail as possible. Specifying little about program execution means that the programs may be nondeterministic. Different runs of the same program may execute statements in different orders, consume different amounts of resources, and even produce different results. Nondeterminism can be employed to derive simple programs, where simplicity is achieved by avoiding unnecessary determinism; such programs can be optimized by limiting the nondeterminism, i.e. by disallowing executions unsuitable for a given architecture.

A UNITY program consists of a declaration of variables, a specification of their initial values, and a set of multiple-assignments. A program execution starts from any state satisfying the initial condition and goes on forever; in each step of execution some assignment statement is selected nondeterministically and executed. Nondeterministic selection is constrained by the following *fairness* rule: every statement is selected infinitely often. A UNITY program describes

what should be done in the sense that it specifies the initial state and the state transformations (i.e. the assignments). A UNITY program does not specify precisely *when* an assignment should be executed – the only restriction is the rather weak fairness condition. Neither does a UNITY program specify *where* (e.g. on which processor in a multiprocessor system) an assignment is to be executed, *how* assignments are to be executed or *how* an implementation may halt a program execution. Thus, UNITY seperates concerns between *what* on the one hand, and *when*, *where* and *how* on the other. The *what* is specified in a program, whereas the *when* ,*where*, and *how* are specified in a mapping.

The computaional model on which UNITY is based on *state-transition systems* [Pnu81, MP83, LT87]. A programming logic and a proof system associated with the model developed in UNITY allow the proof to be seperated from the program text, and developed and studied a proof in its own right.

The specifications, refinement of specifications, proof system and mapping programs to architectures are all based on a semantic model that is assumed to exist in UNITY work. This paper develops such a semantic model for UNITY that reflects aspects of UNITY such as *nondeterminism*, *absence of control flow*, etc.. The semantic model is intended to model the UNITY programming logic and proof system, and to support the UNITY specification. This model is a kind of *state-transition systems* within which *observations* and *actions* of assignments are the basic semantic objects. With this model, it is shown that how the different fairness conditions, termination of a program execution can be defined and how the safety and liveness (progress) properties can be represented.

2 Notes on UNITY

This section presents a subset of the UNITY notation that needed for the development of the semantic model.

- **Primitive Commands**:
  The primitive commands are conditional multiple assignments of the following form:

$$
\begin{aligned}
x_1,\ldots,x_m := e_{11},\ldots,e_{1m} \text{ if } b_1 \\
\sim e_{21},\ldots,e_{2m} \text{ if } b_2 \\
\sim \vdots
\end{aligned}
$$

$\sim e_{n1},\ldots,e_{nm}$ if b_n,

where, all the e's are expressions and the b's are boolean expressions.

Thus, a multiple assignment consists of variable list on the left side and expression lists with corresponding boolean expressions on the right side. If all component simple-expression lists (without boolean expressions) whose associated boolean expressions are $true$ are equal in value, any one of them can be choosen for assignment; if they are not equal in value, then the assignment results in a *failure*; if no boolean expression is $true$, the variable values are left unchanged.

- **Statements**:
  In [CM88], only primitive commands are UNITY statements. For defining different fairness conditions and making the semantic model mathematically elegant, the statements of the language are defined as follows:
  primitive commands are statements, and if S_1 and S_2 are statements, $(S_1[]S_2)$ is a statement. The following equivalences hold:
  $(S_1[]S_2) \equiv (S_2[]S_1)$ and $(S[]S) \equiv S$.

- **Programs**:
  An UNITY program consists of a *program-name*, a *declare-section* which declares the types of the program variables, *initially-section* which defines the initial values of some variables in this program and an *assign-section* which is a statement list, $S_1[]\ldots[]S_n$. (See [CM88] for more details).

  Since the types of variables are going to be ignored in the semantic model, the *declare-section* here is not considered any further here. The initially-section is a set of equations which is *proper* in the sense that it can be used to determine the values of some variables named in the program Here, the initially-section can be generally taken as a predicate about variables in the program. Therefore, a UNITY program can be abstractly denoted as

  $$P = (Pr, L),$$

  where, Pr is a set of predicates over the initial values of the variables named in P, and L is the assign-section of the program, Pr is in fact a set of equations of the form $x = e$, where e is an expression.

In UNITY, there are two different kinds of compositions of programs. The *union* of two programs is obtained by appending their codes together. Unlike union, *superposition* describes modifications of a given program by adding new variables and assignments, but not altering existing assignments. Thus, superposition preserves all the properties of the original program. For detailed definitions of the two kinds of compositions, see Section 4

3 A Semantic Model

3.1 An Informal Overview

As seen in Section 2, an UNITY program contains a statement list. Let S be a statement in such a program. In an execution of S, let each of its variables be represented by its *observed value*, which is the sequence of values assigned to the variable. Thus, each multiple assignment to a set of variables appends an element to the previous observed value of each variable in the set. An execution of S can then be described in terms of the observed values of its variables, and it is sufficient to record the observed values of its variables before and after the execution of each primitive command.

An *observation* of a statement S in a program is the set of observed values of the variables of the program taken at the same instant of time. If the empty sequence λ is the initial observed value of the variables x_1, x_2, y_1 and y_2 for an execution of the statement

$$x_1, x_2 := 1, 2[]y_1, y_2 := 3, 4,$$

then the sequence of the observed values of the x's and y's would be

Observations

x_1	λ	$< 1 >$
x_2	λ	$< 2 >$
y_1	λ	λ
y_2	λ	λ

if $x_1, x_2 := 1, 2$ is selected to be executed, or

Observations		
x_1	λ	λ
x_2	λ	λ
y_1	λ	$< 3 >$
y_2	λ	$< 4 >$

if $y_1, y_2 := 3, 4$ is selected to be executed.

Thus, a statement in a program can be taken as an *action*, each execution of which transforms one observation into another; primitive commands can be taken as *atomic actions*.

Each element in an observed value is either taken from the value space of the programming variables or is a distinguished value representing a particular result of the execution of a statement. For example, execution of the statement

$$x := 3[]y := x + 1$$

will result in y the value of the expression $x + 1$ only when that is defined and $y := x + 1$ is selected to be executed. But if before executing this statement the observed value of x is λ , the value of y is not defined if $y := x + 1$ is selected to be executed, and the execution fails. The failure induces the $\perp$ in all variables. Therefore, the execution of the statement will produce

Observations		
x	λ	$< \perp >$
y	$< v >$	$< v, \perp >$

if λ and $< v >$ are the initial observed values of x and y respectively and $y := x+1$ is selected to be executed.

A *behaviour* of an UNITY program P is an infinite sequence of observations over its variables. The first observation is determined by the initially-section of P and each of the rest is produced from its predecessor by an execution of a statement selected from the statement list of P. A behaviour of a program is *finite* if after some observation in the sequence all the values of the variables appended in the observations keep unchanged. Properties of observations can be found in [JG88, JG89] in more details.

3.2 Observations

Obsrvations instead of states is used as the basic semantic objects. This makes it easy to define atomic actions and composed actions in mathematical way. Let X be a set of program variables with value space V equipped with an equality relation '=' which is the minimum reflexive relation on V. We shall initially ignore the types of the variables, but it is relatively easy to extend the concepts in this paper to include types. Let V^* be the set of all the finite sequences (including the empty sequence λ) over V. In addition to V, we assume a set, $Stop$, of distinguished values ($Stop \cap V$ = Ø): after a variable has taken a value from $Stop$, it can be only assigned a value in $Stop$. Let

$$V^\dagger = \left\{ s \frown d | s \in V^* \wedge d \in Stop^+ \right\},$$

where $Stop^+$ is the set of all finite sequences over $Stop$ without including the empty sequence λ.
Then the set of *observed values* is defined as

$$W = V^* \cup V^\dagger$$

We also denote the set of all the one-element sequences over $V \cup Stop$ as U.

Some functions and predicates on W are needed. In what follows, S, S_1 and S_2 are sequences in W.

λ	the empty sequence;
$\#S$	the length of S ($\#\lambda = 0$);
$S[i]$	the ith element of S ($0 < i \leq \#S$);
$S_1 \preceq S_2$	S_1 is a prefix of S_2;
$S_1 \prec S_2$	S_1 is a proper prefix of S_2;
$S_1 \frown S_2$	the catenation of S_1 and S_2;
$S \frown v$	appending the element v in V to the end of S;
$first(S)$	the first element of S if S is not empty;
$last(S)$	the last element of S if S is not empty;

$current(S)$	the one-element sequence consisting of $last(S)$ if $S \neq \lambda$, and λ otherwise;
$rest(k, S)$	the sequence obtained from S by removing the first k elements if$k \leq \#S$, and λ otherwise;
$rest(S, k)$	the sequence obtained from S by removing the last k elements if $k \leq \#S$, and λ otherwise;
$rest(S_1, S_2)$:	$rest(\#S_1, S_2)$ if $S_1 \preceq S_2$ or $S_2 \preceq S_1$, and S_2 otherwise;
$range(S)$	the range of S, i.e. the set of the elements occurring in S;
$fixed(k, S)$	is $true$ iff $range(rest(k, S))$ is $\{S[k]\}$ or Ø.

With the informal description given in the previous subsection, an *observation* on a set of variables X can be formally defined as a function as follows.

Definition 3.1 *An* **observation** *on X is a function Ob: $X \longrightarrow W$ satisfying*

$$\exists\, x \in X(last(Ob(x)) = \perp) \Rightarrow \forall\, y \in X(last(Ob(y)) = \perp),$$

where Ob can be denoted as the set of pairs $\{(x, Ob(x))|x \in X\}$ and $\perp \in Stop$.

In the following, some of the functions and predicates over W given above are extended to the set of all the observations on X denoted as OB_X, Ob, Ob' are observations and k is an natural number.

- $Ob \preceq Ob'$ iff for each $x \in X$, $Ob_1(x) \preceq Ob'(x)$;
- $Ob_1 \prec Ob'$ iff $Ob_1 \preceq Ob'$ and there is some $x \in X$, $Ob_1(x) \prec Ob'(x)$;
- $fixed(k, Ob) \equiv \forall\, x \in X fixed(k, Ob(x))$;
- $current(Ob)(x) = current(Ob(x))$ for all $x \in X$;
- $rest(k, Ob)(x) = rest(k, Ob(x))$ for all $x \in X$;
- $Ob_1 \frown Ob'(x) = Ob_1(x) \frown Ob'(x)$ for all $x \in X$.

3.3 Actions

An *action* on a set of variables X is a relation on the set of observations OB_X– that is, a set of pairs of observations. If ξ is an action, then $(s, t) \in \xi$ means that executing ξ starting in s will get to the observation t. Thus a statement in a UNITY program can be defined as an action on the program variables, which specifies the transformation defined by the statement.

Definition 3.2 *An* **action** *on X, ξ, is a relation on the set of all the observations on X such that $\forall\, s \in OB_X, \exists\, t \in OB_X, [(s,t) \in \xi]$ and the following conditions are satisfied:*

1. $(s,t) \in \xi \Rightarrow s \preceq t$;
2. $(s,t) \in \xi \Leftrightarrow (current(s), current(s) \frown rest(s,t)) \in \xi$.
3. $\forall\, x \in X[(s,t) \in \xi \wedge range(current(s(x))) = \{\perp\} \Rightarrow t(x) = s(x) \frown \perp]$.

Condition 1 means that executing an action can only extend the observed values of its variables but cannot change any observed value which has already occurred, Condition 2 says that the transformation made by an action only depends on the current values of the observation with which the execution of the action started and Condition 3 implies that an action cannot have any futher effect on a variable after it has taken the value $\perp$.

For an observation s on X and $v \in W$, s^x_v is the function obtained from s such that $(s^x_v(x) = v) \wedge \forall\, y \in X(y \neq x \Rightarrow s^x_v(x) = s(y))$. An action ξ **modifies** a variable x if there is a pair of observations (s,t) in ξ such that $\forall\, y \in X(last(t(y)) \notin Stop)$ and $s(x) \neq t(x)$; ξ **essentially modifies** x if there exists $(s,t) \in \xi$ such that $last(s(x)) \neq last(t(x)) \neq\notin Stop$; ξ **does not read** x if for any $(s,t) \in \xi$ and any observed value v of x such that that s^x_v and t^x_v are valid observations with respect to Definition 3.1, $(s^x_v, t^x_v) \in \xi$; ξ **does not (essentially) access** x if ξ does not (essentially) modify or read x.

Intuitively, x is modified by ξ if it takes value by an assignment in ξ, x is read by ξ if its value is used by an assignment in ξ. For examples, $x := y + 1\ if\ false$ does not modify x; $x := x$ modifies x but does not essentially modify x.

Operations on actions:

For a set X of variables and a subset Y of X, let s and t be actions on X, t^Y_s be the function obtained from s and t such that $\forall\, y \in Y(t^Y_s(y) = s(y)) \wedge \forall\, x \in (X - Y)(t^Y_s(x) = t(x))$. In the following, Act denotes the set of all the actions on X.

- Union: $\cup$: $Act \times Act \longrightarrow Act$,
  $\xi \cup \mu = \{(s,t) | (s,t) \in \xi or (s,t) \in \mu\}$.
- Composition: $\circ$: $Act \times Act \longrightarrow Act$,
  $\xi \circ \mu = \{(s,t) |\, \exists\, t_1[(s,t_1) \in \xi] \wedge [(t_1,t) \in \mu]\}$.

- Closure: *: $Act \longrightarrow Act$,
  $\xi^* = \{(s,t) | \exists\, n \geq 0 [(s,t) \in \xi^n]\}$, where $\xi^{n+1} = \xi \circ \xi^n$ and $\xi^0 = \{(s,s) | s$ is an observation$\}$.

- Augmentation: $\|$: $Act \times Act \longrightarrow Act$,
  for actions ξ and μ, let X_1 and X_2 be the sets of variables that are not modified by ξ and μ respectively,
  $(s,t) \in \xi \parallel \mu$ if $(s, t_s^{X_1}) \in \xi$ and $(s, t_s^{X_2}) \in \mu$, or for any $x \in X$, $t(x) = s(x) \frown \perp$ if there is a $(s,t_1) \in \xi$ such that $\exists\, x \in X(last(t_1(x)) = \perp)$, or there is a $(s,t_2) \in \mu$ such that $\exists\, x \in X(last(t_2(x)) = \perp)$, or there are $(s,t_1) \in \xi$ and $(s,t_2) \in \mu$ such that $(t_1(y) \neq t_2(y))$ for some $y \in X$ which is modified by both ξ and μ.

Intuitively, $x := 0\ if\ false \| x := x + 1$ is equivalent to $x := x + 1$ and $x := x \parallel x := x + 1$ produces $\perp$ in the semantic model.

Definition 3.3 *An action ξ on X, is called* **atomic** *if it satisfies the following conditions:*

1. *(deterministic):* $(s,t_1), (s,t_2) \in \xi \Rightarrow t_1 = t_2$*;*
2. *(one-stepping):* $(s,t) \in \xi \Rightarrow \forall\, x \in X[(t(x) = s(x)) \vee \exists\, v \in U(t(x) = s(x) \frown v)]$.

Theorem 3.1 *For actions ξ and μ, $\xi = \mu$ iff $\forall\, s \in OB_X(\forall\, x \in X(0 \leq \#s(x) \leq 1) \Rightarrow \forall\, t \in OB_X((s,t) \in \xi \Leftrightarrow (s,t) \in \mu)$).*

Proof: It is trivial to show that if $\xi = \mu$, $\forall\, x \in X(0 \leq \#s(x) \leq 1)[(s,t) \in \xi \Leftrightarrow (s,t) \in \mu]$.

To prove that only if $\xi = \mu$, $\forall\, s \in OB_X(\forall\, x \in X(0 \leq \#s(x) \leq 1) \Rightarrow \forall\, t \in OB_X((s,t) \in \xi \Leftrightarrow (s,t) \in \mu))$; we assume that $X = \{x\}$ without loss of generality. Let $(s,t) \in \xi$, if $\#s \leq 1$, we have already got $(s,t) \in \mu$. If $\#s > 1$, from Condition 2 in Definition 3.2, we have $(current(s), current(s) \frown rest(s,t)) \in \xi$, and thus $(current(s), current(s) \frown rest(s,t)) \in \mu$ because $\#current(s(x)) \leq 1$. Again from Condition 2 in Definition 3.2, $(s,t) \in \mu$.

□

Theorem 3.2 *The set of all atomic actions is closed under the* **augmentation**, *that is, if ξ and μ are atomic actions, then so is $\xi \parallel \mu$.*

Proof: Let ξ and μ be atomic actions, X_1 and X_2 be the sets of variables that are not modified by ξ and μ respectively. It is obvious that $\xi \parallel \mu$ is *one-stepping*. Therefore, it is sufficient to show that $\xi \parallel \mu$ is *deterministic*.

Let $(s, t_1), (s, t_2) \in \xi \parallel \mu$, if $\forall\, x(t_1(x) = s(x) \frown \perp)$, then $\forall\, x(last(s(x)) = \perp) \vee \exists\, t[(s, t) \in \xi \wedge \forall\, x(last(t(x)) = \perp)] \vee \exists\, t[(s, t) \in \mu \wedge \forall\, x(last(t(x)) = \perp)]$ or there are $(s, t) \in \xi$, $(s, t') \in \mu$ and y which is modified by both ξ and μ, such that $(t(y) \neq t'(y)$. Since ξ and μ are atomic, it is easy to check that for each case listed above, $\forall\, x(t_2(x) = s(x) \frown \perp)$, that is $t_1 = t_2$. Similarly, if $\forall\, x(t_1(x) = s(x) \frown \perp)$, then $t_1 = t_2$. If for any x, $last(t_1(x)) \neq \perp$, then for any x, $last(t_2(x)) \neq \perp$ and $(s, t^{X_1}_{1s(X_1)}) \in \xi \wedge (s, t^{X_1}_{2s(X_1)}) \in \xi \wedge (s, t^{X_2}_{1s(X_2)}) \in \mu \wedge (s, t^{X_2}_{2s(X_2)}) \in \mu$. Since ξ and μ are atomic, $(s, t^{X_1}_{1s(X_1)}) = (s, t^{X_1}_{2s(X_1)})$ and $(s, t^{X_2}_{1s(X_2)}) = (s, t^{X_2}_{2s(X_2)})$. Hence, $t_1 = t_2$.

□

In the UNITY framework, augmentations are applied only to atomic actions.

Definition 3.4 *The class of* **generated actions** *is defined recursively as follows:*

1. *Atomic actions are generated actions;*
2. *If ξ and μ are generated actions, then $\xi \cup \mu$ is a generated action;*
3. *If ξ and μ are generated actions, then $\xi \circ \mu$ is a generated action;*
4. *If ξ and μ are generated actions, then $\xi \parallel \mu$ is a generated action;*
5. *Generated actions can be obtained only by applying these rules finitely many times.*

Definition 3.5 *An action, ξ, is a* **program action** *if it can be decomposed into the union of a set of atomic actions.*

Theorem 3.3 *The set of all program actions on X is closed under the* **union**, *i.e. if ξ and μ are program actions, $\xi \cup \mu$ is also a program action.*

Proof: Trivial.

□

3.4 Executions

Definition 3.6 *Let X be a set of variables, Π be a set of actions on X and R_0 be an observation on X; then an infinite sequence of observations,*

$$E = R_0 R_1 \ldots R_i \ldots,$$

is an **execution** *of Π with R_0, if for each $i \geq 0$, there exists an action $\xi \in \Pi$, such that $(R_i, R_{i+1}) \in \xi$, and this is denoted as $E = (R_i)$.*

We use $Ex(R_0, \Pi)$ to denote the set of all executions of Π with R_0, and $EX(\Pi)$ to denote the set of all the executions of Π. Later, we will define an UNITY program as a set of program actions. The properties of the program are expressed as assertions over the set of executions. Also, we can treat an execution, $E = (R_i)$, as a function from the set of natural numbers $\aleph$ to the set of observations OB_X such that for all $i \geq 0$, $R_i = E(i)$ and $(E(i), E(i+1)) \in \xi$ for some $\xi \in \Pi$. We use both sequences and functions to represent executions in this paper.

Definition 3.7 *Let Π be a set of actions on X and*

$$E = R_0 R_1 \ldots R_i \ldots$$

is an execution of Π with R_0, E is called a **finite execution** *of Π, if there exist $n \geq 0$ and $m \geq 0$ such that for any $i \geq n$, $fixed(m, R_i) = true$, and if n is the least number for which such an m can be found, the finite execution E is represented as*

$$E = R_0 \ldots R_n.$$

Definition 3.8 *An execution of Π is said to be* **fair**, *if for any $i \geq 0$ and $\xi \in \Pi$, there is some $k \geq i$ such that $(R_k, R_{k+1}) \in \xi$.*

We use $Fex(R_0, \Pi)$ to denote the set of all fair executions of Π with R_0, and $FEX(\Pi)$ to denote the set of all the fair executions of Π.

Note that if a statement is defined as an action while a primitive command is defined as an atomic action, the definition of fairness seems to be weaker than that given in [CM88] in the following sense: a UNITY program in [CM88] can be defined as a set of atomic actions Π, and to say that an execution E of Π is fair just means that E could be obtained by executing each atomic action in

Π infinitely many times, but possibly also if certain atomic actions in Π were executed only finitely many times. On the other hand, the fairness condition given here is abstract, and is sufficient for reasoning about programs and justifying implementations of programs (see Section 4). There can be many different sets Π that give the same same set of executions. For example, replacing two actions ξ and μ by the single action $\xi \cup \mu$ does not change the set of executions but may change the set of fair executions. Thus, there can be many equivalent ways to write essentially the same program.

In [MP83] this particular form of fairness is called *justice* [GP89]. Some other alternative forms of fairness [Fra86] can be also be defined. Specially, let $\Pi = \Pi_1 \cup \Pi_2$. An execution E of Π is said to be **fair with respect to** Π_1, if for each $i \geq 0$ and each action $\xi \in \Pi_1$, there exists $k \geq i$ such that $(E(k), E(k+1)) \in \xi$. E is said to **bounded with respect to** Π_1, if there exists $i \geq 0$ such that for any $k \geq i$,$(E(k), E(k+1)) \in \xi$ for some $\xi \in \Pi_2$. Such forms of fairness can be used to define the sumption that faults cannot occur infinitely often when dealing with fault-tolerance [Liu89]. The logic for specification and proof of correctness of programs is of course based on specific fairness. The UNITY logic is based on *justice*.

When we deal with the semantics of programming languages, we are usually interested only in the executions of sets of generated actions. For UNITY, we concentrate on the executions of sets of program actions.

4 The Semantics of the UNITY Notations

- The semantics of expressions:
  Let X be the set of the variables used in a program, $Expr$ be the set of all the expressions over X and V, then the semantic function for the expressions is defined as:

  $$\mathcal{E}\colon Expr \longrightarrow (Func(V \cup Stop) \longrightarrow V \cup Stop),$$

  where $Func(S)$ is the set of all the functions with finite arguments over S , and for each expression $e(x_1, \ldots, x_n)$ with x_1, ..., x_n occurring within it, $\mathcal{E}(e(x_1, \ldots, x_n))$ is determined by the operations used in e and satisfies the following *strictness condition*:

$$e(a_1, \ldots, a_n) = \perp, \text{ if some } a_i = \perp.$$

where there is no confusion, we also use the expression e to represent the value of $\mathcal{E}(e)$.

- The semantics of the UNITY Statements:
  Let $Statement$ denote the set of all the UNITY statements and $Progact$ denote the set of all the program actions, the semantic function for statements is defined recursively as
  $\mathcal{S}$: $Statement \longrightarrow Progact$:

  1. Basis: For a primitive command p,

     $x_1,\ldots,x_m$:= $e_{11},\ldots,e_{1m}$ if b_1
     $\sim e_{21}, \ldots,e_{2m}$ if b_2
     $\sim \vdots$
     $\sim e_{n1},\ldots,e_{nm}$ if b_n,

     $\mathcal{S}(p)$ consists of the pairs (s,t) satisfying :

     (a) $\forall\, x \in X(last(x) = \perp \Rightarrow t(x) = s(x) \frown \perp)$;
     (b) $\forall\, i \leq n(b_i(current(s)) = false) \Rightarrow t = s$;
     (c) if there is a k such that $b_k(current(s)) = true$, and $s(y) = \lambda$ for some y named in e_{ki} for some $i \leq m$, then $\forall\, x \in X(t(x) = s(x) \frown \perp)$;
     (d) if there are $i, j \leq m$ such that $i \neq j \wedge x_i = x_j$ and there is a $k \leq n$ such that $b_k(current(s)) = true$, but $e_{ki} \neq e_{kj}$, then $\forall\, x \in X(t(x) = s(x) \frown \perp)$;
     (e) if there are $k, l \leq n$ such that $b_k(current(s)) = b_l(current(s)) = true$, but there is an $i \leq m$ such that $e_{ki} \neq e_{li}$, then $\forall\, x \in X(t(x) = s(x) \frown \perp)$; otherwise
     (f) if there is a $k \leq n$ such that $b_k(current(s)) = true$, then $\forall\, i \leq m(t(x_i) = s(x_i) \frown e_{ki})$ and $t(x) = s(x)$ for any x that is different from each x_i.

  2. Recursion: $\mathcal{S}(S_1[]S_2) = \mathcal{S}(S_1) \cup \mathcal{S}(S_2)$.

- The Semantics of Statement Lists:
  A statement list is of the form as:

  $$L = S_1[] \ldots []S_n.$$

  The semantics of L is defined as follows:

  $$\mathcal{L}(L) = \{\mathcal{S}(S_1), \ldots, \mathcal{S}(S_n)\}.$$

  So the semantics of a statement list is the set of the program actions determined by the statements of the list. It is reasonable to semantically treat staements and statement lists at different levels because of the fairness conditions. Note that for statement lists, L_1 and L_2,

  $$\mathcal{L}(L_1[]L_2) = \mathcal{L}(L_1) \cup \mathcal{L}(L_2).$$

  It is not very essencial for us to consider the *empty* statement list $NULL$, i.e. a list without any statement. If we have to consider it, just let $\mathcal{L}(NULL)$ = Ø.

  Now we can define the set of **behaviours** of a statement list, L, as the set of executions of $\mathcal{L}(L)$, and denote it as $\mathcal{BEH}(L)$, thus,

  $$\mathcal{BEH}(L) = EX(\mathcal{L}(L)).$$

  In the same way, we can define the set of **fair behaviours** of a statement list L, and denote it as $\mathcal{FBEH}(L)$.

- The Semantics of UNITY Programs:
  We define the semantics of an UNITY program as a set of behaviours of the statement list contained within it , in which each behaviour satisfies the initial conditions defined in the initially-section of the program and some fairness conditions.

  For a UNITY program $P = (Pr, L)$, we say a behaviour of L, $F \in \mathcal{BEH}(L)$ **satisfies** the initial condition Pr, if for all $x \in X(\#F(0) \leq 1)$ and $Pr[F(0)] = true$, and $F \underline{Sat} Pr$ denotes that F satisfies Pr. Here, the meaning of $Pr[F(0)] = true$ is just the same as that in first order logic.

Now we can define alternative semantics for UNITY programs based on different fairness conditions.

Definition 4.1 *Let $P = (Pr, L)$ be an UNITY program,*

1. *The* **loose semantics** *of P is defined as the set of the behaviours of L that satisfies the initial condition Pr, of P, i.e.*

$$\mathcal{BEH}(P) = \{F | F \in \mathcal{BEH}(L) \wedge F \underline{Sat} Pr\};$$

2. *The* **fair semantics** *of P is defined as the set of of the fair behaviours of L that satisfies the initial condition Pr of P, i.e.*

$$\mathcal{FBEH}(P) = \{F | F \in \mathcal{FBEH}(L) \wedge F \underline{Sat} Pr\};$$

Note that if $Pr = false$ in $P = (Pr, L)$, then

$$\mathcal{BEH}(P) = \mathcal{FBEH}(P) = \emptyset.$$

The fair semantics of P can be implemented by executing each statement in L infinitely many times. We can also define some other alternative semantics for UNITY programs. Specially, let $P = (Pr, L_1[]L_2)$. We say that a behaviour, F, of $L = L_1[]L_2$ is **fair with respect to** L_1, if F is fair with respect to $\mathcal{L}(L_1)$. F is **bounded** with respect to L_1, if F is bounded with respect to $\mathcal{L}(L_1)$. F is bounded with respect to L_1 means that F can be obtained by executing L_1 only finite times.

Now let us look into composition and superposition of programs. If $P_1 = (Pr_1, L_1)$ and $P_2 = (Pr_2, L_2)$ are programs, the **union** of P_1 and P_2 is written as $P_1[]P_2$. We use $\mathcal{B}$ to denote any one of the semantic functions based on different fairness conditions, such as $\mathcal{BEH}$ and $\mathcal{FBEH}$ etc, then we define

$$\mathcal{B}(P_1[]P_2) = \mathcal{B}(Pr_1 \wedge Pr_2, L_1[]L_2).$$

Note this definition is consistent with the assumption that there are no inconsistencies in the definitions of variables.

For a program $P = (Pr, L)$, and a primitive command s in P, if r is a primitive command, let $P^s_r = (Pr, L^s_r)$ represent the program Q that is obtained from P by replacing s in P by r. We can define an **augmentation** of a program $P = (Pr, L)$ with Pr' and a primitive command r as follows:

$$\mathcal{A}(P, s, Pr', r) = (Pr \wedge Pr', L^s_{s||r}),$$

where, s is a primitive command in P, r is a primitive command which does not modify any variable named in P and Pr' is a prdicate about the initial values of the variables named in r. The program P in the above equation is called the *underlying program*.

Now we have the *semantics of an augmentation* of a program as

$$\mathcal{B}(\mathcal{A}(P, s, Pr', r)) = \mathcal{B}((Pr \wedge Pr', L^s_{s\|r})),$$

i.e. relacing the atomic action determined by s by the atomic action determined by $s \,\|\, r$.

After modelling the UNITY programming logic, it is easy to prove the **Union Theorem** in [CM88], but the **Superposition Theorem** in [CM88] is required to be restated in our framework as: *Every property of the underlying program is a property of the augmentation if no failure is introduced by the superposed variables*.

5 Modelling the UNITY Programming Logic

This section shows that within the semantic model given in this paper, the UNITY programming logic can be modelled and thus *safety* and *progress* properties of a program can be described. In this section, all predicates used in the logic are about observations on specified sets of variables. For each variable x withvalue space V_x, a sequence vriable $\overline{x}$ is introduced whose value space is $W_x = V_x^* \cup V_x^\dagger$. A predicate p over OB_X names only variables in X or some $\overline{x}$ for $x \in X$. Let p be a predicate over OB_X and Ob be an observation in OB_X, $Ob \models p$ iff $p[Ob]$ is $true$, where $p[Ob]$ is obtained by replacing each occurrence of $x \in X$ by $last(Ob(x))$ and each occurrence of $\overline{x}$ by $Ob(x)$.

Most properties of a UNITY program are expressed using assertions of the form $\{p\}S\{q\}$, where S is universally or existentially quantified over the statements (here statements are assignment statements) of the program. $\{p\}S\{q\}$ denotes that an execution of statement S in any state (observation) that satisfies predicate p results in a state (observation) that satisfies predicate q, if execution of S terminates. Properties that hold for all program observations during execution are defined using only universal quantification. Properties that hold eventually are defined using existential quantification as well.

Traditionally, a program property is regarded as either a *safety* or a *progress* property. Existential quantification over program statements is essential in stating progress properties, whereas safety properties can be stated using only universal quantifications over statements (using the initial condition). For describing certain kinds of properties that should be considered with any program, the terms, *unless, stable, invariant, ensures, leads-to* and *fixed point*, are introduced and theorems about them are derived in UNITY. Therefore, the essential part of modelling this logic is modelling assertions of the form $\{p\}S\{q\}$.

Since statements are defined as actions, $\{p\}S\{q\}$ is defined as the triple $\{p\}\mathcal{S}(S)\{q\}$. A general definition of the *Hoare logic of actions* is needed [Lam87].

Let ξ be an action on X, p and q be predicates over OB_X; the Hoare triple $\{p\}\xi\{q\}$ is defined to mean $\forall(s,t) \in \xi[(s \models p) \Rightarrow (t \models q)]$. In other words, $\{p\}\xi\{q\}$ asserts that if p is $true$ in observation s and executing ξ in observation s can produce observation t, then q is $true$ in t. It is easy to check that the usual rules for reasoning about Hoare triples [Hoa69] hold for triples of actions. Some of these are listed as follows:

- $\{p\}\xi\{true\}$;
- $\{false\}\xi\{q\}$;
- $\{p\}\xi\{false\} \Rightarrow \neg p$;
- $\{p\}\xi\{q\}, \{p'\}\xi\{q'\} \Rightarrow \{p \vee p'\}\xi\{q \vee q'\}, \{p \wedge p'\}\xi\{q \wedge q'\}$;
- if $p' \Rightarrow p$, $\{p\}\xi\{q\}$ and $q \Rightarrow q'$, then $\{p'\}\xi\{q'\}$;
- if $\{p\}\xi\{q\}$ and $\{p'\}\,\mu\{q'\}$, then $\{p \vee p'\}\xi \cup \mu\{q \vee q'\}$ and $\{p \wedge p'\}\xi \parallel \mu\{q \wedge q'\}$; note the special case when $p = p'$ and $q = q'$.
- if $\{q\}\xi \cup \mu\{q\}$, then $\{q\}\xi\{q\}$ and $\{q\}\,\mu\{q\}$.

For a given set of actions (program actions) Π, $p\ unless\ q$ in Π is defined as follows:

$$p\ unless\ q \equiv < \forall\, \xi \in \Pi(\{p \wedge \neg q\}\xi\{p \vee q\}) >.$$

Thus if p is $true$ at some point in an execution of Π and q is not, in the next step (i.e. after execution of an action) p remains $true$ or q becomes $true$. Hence, if p holds at any point during an execution of Π, then either

- q never holds and p continues to hold forever, or
- q holds eventually (it may holds initially when p holds) and p continues to hold at least until q holds.

This can be formalized and easily proved as the following theorem.

Theorem 5.1 *$p\ unless\ q$ in Π iff for each execution E of Π and any $i \geq 0$, $(p \wedge \neg q)[E(i)] \Rightarrow (p \vee q)[E(i+1)]$.*

Corollary 1 *If $p\ unless\ q$ in Π, then for any any execution E of Π and $i \geq 0$,*
$p[E(i)] \Rightarrow$
$< \forall j : j \geq i :: (p \wedge \neg q)[E(j)] >$ (*i.e. $p \wedge \neg q$ holds forever*) $\vee$
$[< \exists k : k \geq i :: q[E(k)]$ (*i.e. q holds eventually*) $\wedge$
$< \forall j : i \leq j < k :: (p \wedge \neg q)[E(j)] >$ (*i.e. until then $p \wedge \neg q$ holds*) $>]$.

□

The special cases of $unless$ are *stable* and *invariant*. For a given set of actions Π,

- p is stable $\equiv p\ unless\ false$
- q is invariant $\equiv$ (initial condition $\Rightarrow q$) $\wedge$ q is stable

We say that an action ξ *leaves p stable* if and only if $\{p\}\xi\{p\}$ holds. For example, every action leaves $\forall x \in X(last(ob(x)) = \perp)$ stable. If ξ leaves both p and q stable, then it leaves $p \wedge q$ and $p \vee q$ stable as well; if both ξ and μ leave q stable, then $\xi \cup \mu$ leaves p stable; if ξ does not modify the variables in p, then ξ leaves both $p \vee \forall x(last(ob(x)) = \perp)$ and $\neg p \vee \forall x(last(ob(x)) = \perp)$ stable; if ξ leaves p stable and μ leaves q stable, then $\xi \cup \mu$ leaves $p \vee q$ stable and if no variable can be modified by both ξ and μ, $\xi \parallel \mu$ leaves $p \wedge q$ stable. p is stable in Π iff each action in Π leaves p stable.

The *ensures* relation (over predicates) is used to define the most basic progress properties of programs. For a given set of actions (program actions), Π, $p\ ensures\ q$ is defined as follows:

$$p\ ensures\ q \equiv (p\ unless\ q \wedge < \exists \xi : \xi \in \Pi :: \{p \wedge \neg q\}\xi\{q\} >).$$

Thus if p is $true$ at some point in an execution of Π, p remains $true$ as long as q is $false$, and eventually q becomes $true$ *if the execution is fair*. Hence we have

Theorem 5.2 $p\ ensures\ q$ *holds in* Π *iff for any fair execution* E *of* Π *and* $i \geq 0$,

$$p[E(i)] \Rightarrow < \exists\, j : j \geq i :: q[E(j)] \wedge < \forall\, k : i \leq k < j :: p[E(k)] >>$$

□

The *leads-to* ($\longmapsto$) relation over predicates is defined by $ensures$ and inference rules [CM88]. In terms of action-executions, $p \longmapsto q$ holds in Π if for any fair execution E of Π and $i \geq 0$,

$$p[E(i)] \Rightarrow < \exists\, j : j \geq i :: q[E(j)] >.$$

Finally, the *fixed point* FP of Π is defined as : for any execution E of Π and $i \geq 0$,

$$FP[E(i)] \equiv < \forall\, j : j \geq i :: current(E(i)) = current(E(j)) >.$$

Obviously, FP is reachable (i.e. such an i exists in the above equivalence) for E iff E is an finite execution.

It is straightforward (but tedious) to prove the validity in our framework of the rules of the UNITY proof system and the theorems about *ensures, leads-to, stable, invariant and fixed point*. We leave these to the interested reader.

6 Conclusions and Discussions

The basic semantic objects of our approach are observed values of program variables and actions - relations over sets of observed values. The purpose of introducing actions into the model is to formalize alternative fairness conditions so as to obtain alternative semantics for programs. The semantic model has been constructed for justifying the UNITY specification and proof system. Obviously, specifications and proof systems heavily depend upon the assumed fairness conditions.

In fact, the semantic model established in this paper is quite language independent. It is easy to be extended to model conventional programming language constructs and architectures [JG88, JG89]. Therefore, this semantic model could

be suitable for justifying proofs of the correctness of mapping UNITY programs to alternative architectures.

The proposed semantic model could also support the techiniques for developing fault-tolerant systems that are presented in UNITY. And some concepts, such as "an action ξ does not (effectively) modify a variable x", might be useful for describing properties of faulty actions, e.g to show that a *faulty action* does not (essentially) modify a *safe variable*, e.g. a variable used for checkpointing. For programs $P_1 = (Pr_1, L_1)$ and $P_2 = (Pr_2, L_2)$, we can define for $P_1[]P_2$ the semantics that is *fair with respect to* L_1 and *bounded* with respect to L_2. When taking P_2 as the program which simulates the specified hardware faults, some properties of its behaviour could be described. Furthermore, this semantics fits the sumption that faults can only occur finitely often. This model is beeing used as the basis for developing some techniques for fault-tolerance within the UNITY framework [Liu89].

Acknowledgment

I wish to thank my supervisor, Prof. Mathai Joseph, for his constant encouragement, guidance, and his comments on earlier versions of this report as well. My thanks also go to my colleagues, A. Goswami and A.M. Lord, for the helpful discussion during this work.
