Abstract

Photovoltaics based on tin halide perovskites have not yet benefitted from the same intensive research effort that has propelled lead perovskite photovoltaics to >20% power conversion efficiency, due to the susceptibility of tin perovskites to oxidation, the low energy of defect formation and the difficulty in forming pin-hole free films. Here we report CsSnI₃ perovskite photovoltaic devices without a hole-selective interfacial layer that exhibit a stability ~10 times greater than devices with the same architecture using methylammonium lead iodide perovskite, and the highest efficiency to date for a CsSnI₃ photovoltaic: 3.56%. The latter results in large part from a high device fill-factor, achieved using a strategy that removes the need for an electron blocking layer or an additional processing step to minimise the pinhole density in the perovskite film, based on co-depositing the perovskite precursors with SnCl₂. These two findings raise the prospect that this class of lead-free perovskite photovoltaic may yet prove viable for applications.

Introduction

Lead-free perovskite photovoltaics (PPVs) using tin halide as the light harvesting semiconductor have not yet benefitted from the same intensive research effort that has propelled lead PPVs from a power conversion efficiency (η) of $\sim 3.8\%$ in 2009¹ to $>20\%$ today², because of the susceptibility of tin to oxidation from the 2+ to the 4+ oxidation states upon exposure to air, a transformation that does not occur easily in lead perovskites.^{3,4} Consequently, the record η for tin halide PPVs lags behind that of lead PPVs at $\sim 6\%$, achieved using $\text{CH}_3\text{NH}_3\text{SnI}_3$ sandwiched between a mesoporous TiO_2 hole-blocking layer (HBL) and doped spiro-OMeTAD electron blocking layer (EBL).^{5,6} The low energy of formation of tin array vacancies in tin halide perovskites has also proved problematic, making it difficult to achieve high device fill-factor (FF) due to high rates of defect mediated charge carrier recombination.^{7,8} Similar to the case of lead perovskites, a further challenge has been in achieving solution processed thin films of tin perovskites with a low density of pin-hole defects, to avoid undermining device FF .⁹ Beyond being lead-free, tin halide perovskites offer a number of properties which make them attractive for use in PPVs provided the challenge with stability can be addressed, including narrower band gaps than their lead analogues (1.3-1.4 eV)^{10,11}, low exciton binding energies (~ 18 meV)^{12,13} and high charge mobilities^{11,14,15}.

To date reports relating to the use of tin halide perovskites as the light harvester in PPV devices^{5,6,8,9,16-21} are relatively few in number, and the η has primarily been limited by a sub-optimal FF .^{5,6,8} Kumar *et al.*⁸ have shown that PPVs based on CsSnI_3 sandwiched between a TiO_2 HBL and triphenylamine EBL ($FF \sim 0.3$) are stable when stored under nitrogen, although the stability in air and/or under continuous illumination was not reported. Hao *et al.*⁶ have shown that after 24 hours under nitrogen the η of devices based on $\text{CH}_3\text{NH}_3\text{SnI}_3$ sandwiched between a TiO_2 HBL and spiro-OMeTAD EBL ($FF \sim 0.48$) was reduced by 64%, even with encapsulation. Similarly, Noel *et al.*⁵ reported that PPVs based on $\text{CH}_3\text{NH}_3\text{SnI}_3$ with the same charge selective interlayers ($FF \sim 0.5$) degrade within minutes

when tested under ambient conditions, and Zhang *et al.*²¹ have reported that unencapsulated PPV devices based on $\text{HC}(\text{NH}_2)_2\text{SnI}_2\text{Br}$, using PEDOT:PSS and PC_{61}BM charge extraction layers, failed within minutes of exposure to air.

Recently we have shown how the efficiency of PPV devices based on the black polymorph of CsSnI_3 perovskite; (B)- γ CsSnI_3 , sandwiched between a fullerene HBL and copper iodide EBL, can be improved by incorporating an excess of SnI_2 into the CsSnI_3 film¹⁹ - The B- γ phase is of most relevance for photovoltaic applications because it exists below 89°C .¹¹ Unfortunately, the stability of those devices was relatively poor with a $\geq 30\%$ loss in η when stored in the dark in ambient air for 1 hour.¹⁹ Herein we have extended this investigation to explore the potential of SnF_2 , SnCl_2 and SnBr_2 additives in CsSnI_3 based PPVs, which has yielded some important new findings that enable the device fabrication process and architecture to be simplified, whilst simultaneously greatly increasing η . We show that SnCl_2 stands out as being a particularly beneficial additive, and that simplifying device architecture by removing the EBL dramatically improves device stability. Crucially, removal of the EBL layer does not reduce device η when SnCl_2 additive is co-deposited with the CsSnI_3 layer.

Probing B- γ CsSnI_3 film structure and stability

It is known that B- γ CsSnI_3 degrades to the zero-dimensional Sn(IV) salt Cs_2SnI_6 in ambient air and that the absorption coefficient of Cs_2SnI_6 in the visible spectrum is a factor of 10 times smaller than that of B- γ CsSnI_3 .¹⁴ Consequently, it is possible to monitor the oxidation of thin films of CsSnI_3 in air by measuring the evolution of the electronic absorption spectrum with time, as shown in Figures 1a and 1b.

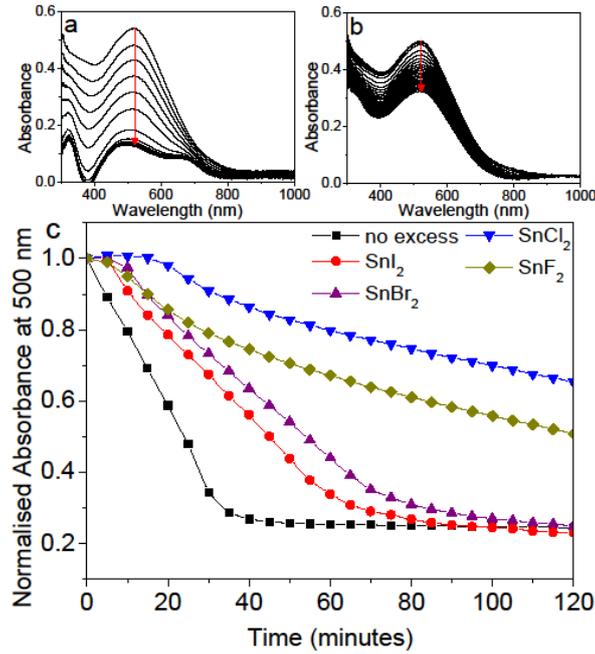

Figure 1 | Evolution of the absorption spectrum of CsSnI₃ films with different tin halide additives in ambient air. **a** CsSnI₃; **b** CsSnI₃ + 10% SnCl₂; and **c** normalised absorbance at 500 nm for CsSnI₃ with 10 mol% of SnI₂, SnBr₂, SnCl₂ or SnF₂, and with no tin halide additive. In all cases the CsSnI₃ solution concentration was 8 wt% which resulted in a film thickness of ~50 nm. All films supported on indium tin oxide (ITO) coated glass. The red vertical lines indicate the direction of change with increasing time in ambient air. [See Supplementary Discussion]

It is evident from Figure 1c that of the four tin halides investigated SnCl₂ results in the highest film stability. Based on the time taken for the absorbance at 500 nm to reduce by 30%, films with SnCl₂ are more stable by a factor of ~3.7 times as compared to CsSnI₃ films with 10 mol% excess SnI₂, and a factor of ~6.7 times compared to films with no tin halide additive. The scanning electron microscope (SEM) images in Figure 2 show that the former cannot be attributed to a difference in film porosity because films prepared with 10 mol%

SnCl_2 have a comparable or higher pin-hole density to films prepared with 10 mol% excess SnI_2 , SnBr_2 or SnF_2 .

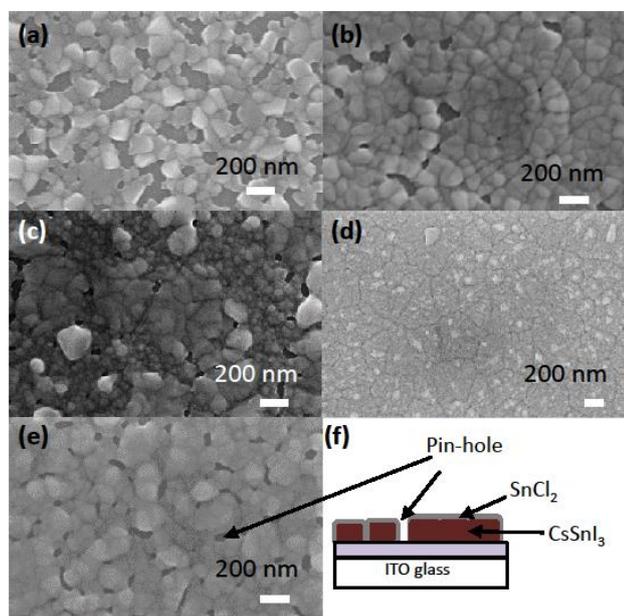

Figure 2 | SEM images of CsSnI_3 films on ITO glass prepared with different tin halide additives. **a** no tin halide additive, **b** 10 mol% added SnI_2 , **c** 10 mol% added SnBr_2 , **d** 10 mol% added SnF_2 , **e** 10 mol% added SnCl_2 . **f** Schematic diagram of proposed film structure in case (e): CsSnI_3 crystallites capped with a thin SnCl_2 layer (see later discussion for the justification of this model).

Corroborating evidence for the large improvement in CsSnI_3 film stability when prepared with 10 mol% SnCl_2 is provided by the evolution of the X-ray diffraction (XRD) pattern of thin films with time exposed to ambient air; Figure 3 and Supplementary Figure 1.^{11,22} Figure 3a shows how the intensity of one of the most intense reflections; the (202) Bragg peak, in the B- γ CsSnI_3 diffraction pattern, disappears completely with time, and so this peak serves as a good probe for monitoring the oxidation of B- γ CsSnI_3 to Cs_2SnI_6 in air. It is evident from a comparison of Figures 3a & 3d that addition of SnCl_2 dramatically improves film stability, since after 3 hours of air exposure this peak has ~80% of its starting

intensity, whilst it has almost completely disappeared for the CsSnI₃ film prepared with no tin halide additive.

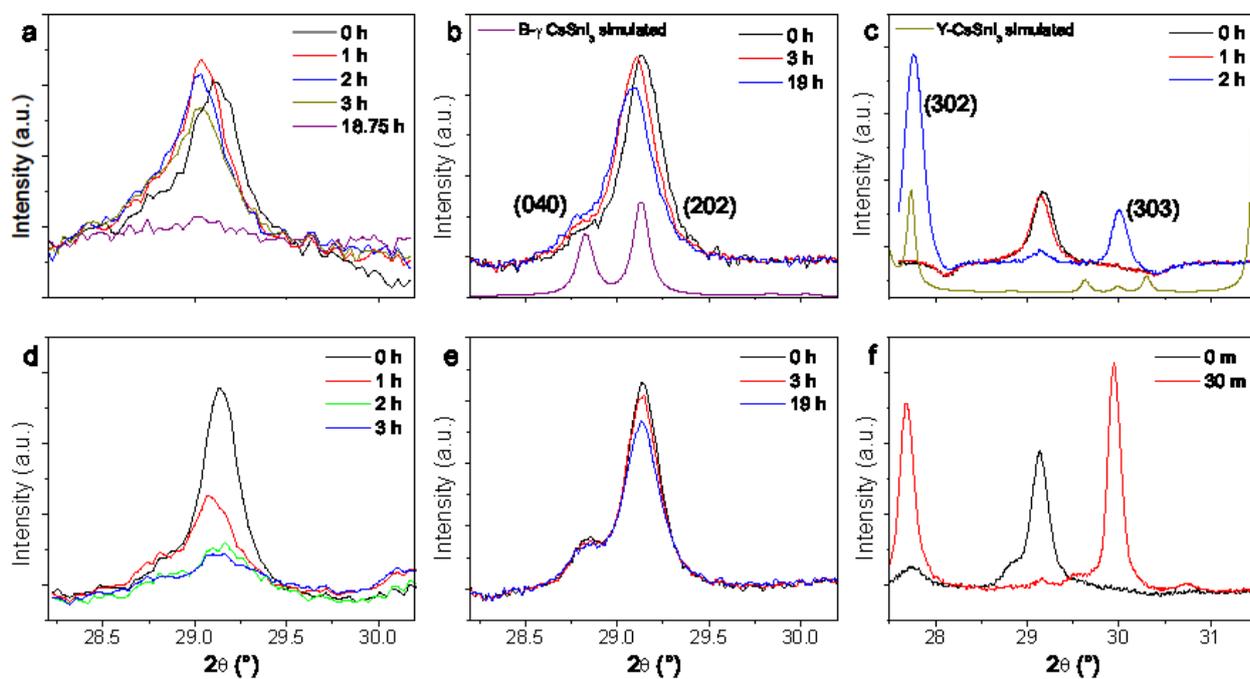

Figure 3 | Evolution of XRD patterns of CsSnI₃ films with and without SnCl₂ additive under different conditions. XRD patterns of thin films of CsSnI₃ prepared with 10 mol% SnCl₂ additive with exposure to; **a** 25% humid air, **b** dry air, and **c** humid nitrogen. XRD patterns of thin films of CsSnI₃ exposed to **d** 25% humid air, **e** dry air, and **f** humid nitrogen.

It is evident from Figures 3b and 3e that B- γ CsSnI₃ is stable in dry air, but converts to the yellow phase (Y-CsSnI₃) in a humid nitrogen atmosphere (Figure 3c and 3f). It is therefore only with the combined action of water and oxygen that Cs₂SnI₆ is formed, which is in agreement with a study of bulk samples reported by Stoumpos *et al.*¹⁵ Notably, Cs₂SnI₆ is a narrow band gap semiconductor with a high electron and hole mobility,^{14,23,24} properties that are very different from those of the decomposition products of lead perovskites.

High resolution X-ray photoelectron spectroscopy (HRXPS) analysis reveals that there is only one Cl 2p environment in CsSnI₃ films prepared with 10 mol% SnCl₂ which has

the same binding energy as for SnCl_2 (Figure 4), consistent with the Cl not being incorporated into the perovskite structure. This suggests that the SnCl_2 is present as a thin film or layer of particles at the perovskite crystallite surfaces as schematically illustrated in Figure 2f. To confirm this hypothesis we have measured the atomic percentage of the different elements that make up the surface of a compact film of CsSnI_3 with 10 mol% SnCl_2 (Supplementary Figure 2) and a thickness of ~ 80 nm, using HRXPS for angles of X-ray incidence of 90° and 30° . Reducing the incident angle halves the sampling depth from ~ 8 nm to ~ 4 nm. For an angle of incidence of 90° the Cl percentage composition is 36.4% (Supplementary Table 1), which is several times higher than would be expected if Cl was evenly distributed throughout the thickness of the film. For an angle of incidence of 30° the Cl percentage increases to 42.9%, while the I percentage decreases from 18.8% to 15.3% and the Cs percentage decreases from 21.9% to 18.1%, compelling evidence that the SnCl_2 is concentrated at the surface of the CsSnI_3 crystallites. Further direct evidence for this conclusion is provided by argon ion sputtering the film surface (Supplementary Figure 3), since the atomic percentage Cl decreases rapidly as the surface is etched, whilst the I concentration increases and then saturates. The conclusion that Cl is not incorporated into the CsSnI_3 lattice is also consistent with the observation that solid solutions of $\text{CsSnI}_{3-x}\text{Cl}_x$ are not formed from stoichiometric DMF solutions of the halide precursors.²⁵ The latter likely stems from the large difference in ionic radii between Cl and I (1.81 Å for Cl and 2.2 Å for I),²⁶ and/ or the very different structures of CsSnCl_3 and CsSnI_3 at room temperature, which are monoclinic and orthorhombic respectively.²⁵ Additionally Peedikakkandy *et al.*²⁵ have shown that a processing temperature of 70°C is needed to form CsSnCl_3 from DMF solutions, which may explain why we do not find evidence for the presence of the CsSnCl_3 perovskite when processing at room temperature. When films of SnCl_2 alone or CsSnI_3 with 10 mol% SnCl_2 are exposed to ambient air for one hour the Cl 2p peaks in both spectra shift to higher binding energies by the same amount (Figure 4a - lower & 4b - lower), and the intensities of the two weak O1s peaks at 530.7 eV and 532.1 eV (Supplementary Figure

4(b)), assigned to SnO_2 ²⁷ and H_2O , respectively, is increased by ~ 10 -fold. The insight as to the differing roles of water and oxygen provided by the XRD patterns, together with the changes in the XPS spectra upon exposure to air, are consistent with the SnCl_2 surface layer functioning as a desiccant which sacrificially oxidises slowing the oxidation of the underlying CsSnI_3 by H_2O , since SnCl_2 is known to form a stable hydrate ($\text{SnCl}_2 \cdot 2\text{H}_2\text{O}$) as well as oxidising to form SnO_2 .²⁸

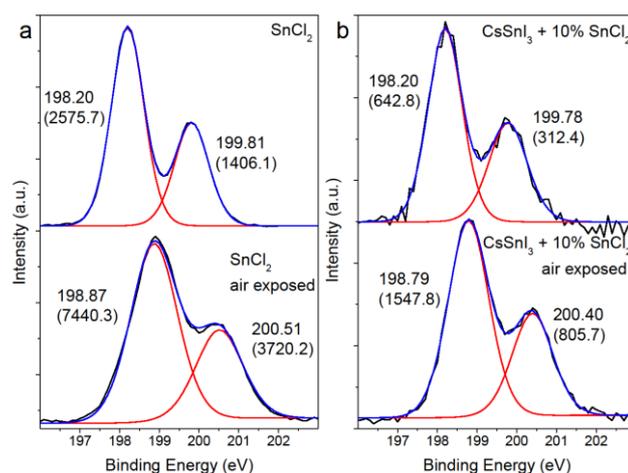

Figure 4 | HRXPS Cl 2p spectra of films of SnCl_2 and $\text{CsSnI}_3 + 10 \text{ mol}\% \text{SnCl}_2$ before and after exposure to ambient air. **a** SnCl_2 with and without 1 hour of air exposure; **b** $\text{CsSnI}_3 + 10 \text{ mol}\% \text{SnCl}_2$ with and without 1 hour of air exposure. The measured spectra, peak deconvolution and the sum of the fitted peaks are given by black, red and blue lines respectively. Fitting performed using CasaXPS software (see Methods Section). Peak positions and intensities labelled on figures.

Photovoltaic device studies

To test if the improvement in film stability towards air exposure translates into improved stability in PPVs, devices with a simplified architecture were fabricated, based on a planar heterojunction using PC_{61}BM as the HBL and CsSnI_3 as the light harvesting layer. This

structure simplifies device fabrication and reduces the number of parallel degradation pathways that can complicate the interpretation of device stability studies. A simplified architecture is also attractive from a commercial perspective, since fabrication costs typically increase with increasing number of processing steps.²⁹ Of the four additives; SnCl₂, SnI₂, SnBr₂ and SnF₂, PPV devices using SnBr₂ and SnF₂ exhibited poor device performance with $\eta \leq 0.4\%$ (Supplementary Table 2) and/or poor device yield and so were not investigated further. Initially SnCl₂ loadings of 5, 10 and 15 mol% were investigated (Supplementary Figure 5 and Supplementary Table 3), and a loading of 10 mol% was found to give the highest yield of working devices combined with a narrow photocurrent spread. Consequently 10 mol% tin halide is the additive loading used in all studies hereafter described. Importantly, the current-voltage characteristics of devices recorded in forward and reverse sweep for a range of starting voltages and scan rates exhibit no significant hysteresis (Supplementary Figure 6).

Immediately after fabrication, devices with a SnCl₂ additive are 60-70% more efficient than those using SnI₂ and a factor of 4 times more efficient than without tin halide additive, due to higher J_{sc} , V_{oc} and FF ; Supplementary Table 4. Importantly, when stored under nitrogen (< 5 ppm O₂ and < 1 ppm H₂O) there are further large improvements in the η of devices with tin halide additives, on the time scale of weeks to several months (Figures 5a&b (Supplementary Table 4) & 5c&d (Supplementary Table 5)). Indeed, the onset of significant improvements begins after only 1 week with ~10% improvement in V_{oc} and FF (Supplementary Figure 7(a)), although there is no change in either the electronic absorption spectrum or X-ray diffraction pattern of the perovskite film (Supplementary Figure 7(b)&(c)). Notably this additional improvement is particularly pronounced for devices that have a low shunt resistance when tested immediately after fabrication, as shown in Figures 5c&d (Supplementary Table 5).

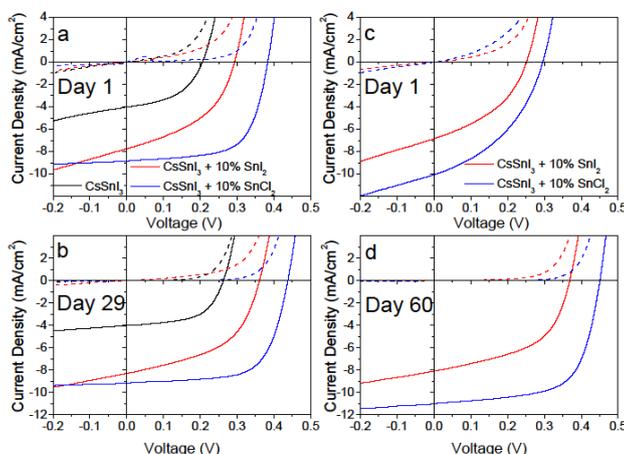

Figure 5 | Current-voltage (*JV*) characteristics of CsSnI₃ PPVs before and after a period of extended storage under nitrogen. Representative *JV* characteristics for devices with the structure: ITO|CsSnI₃|PC₆₁BM|BCP|Al using CsSnI₃ with 10 mol% SnCl₂, 10 mol% SnI₂ and with no additive as the light harvesting layer and PC₆₁BM as the HBL. Devices were tested immediately after fabrication (a and c) and after storage under nitrogen for an extended period (b and d).

To our knowledge the *FF* is the highest achieved for a tin halide PPV; mean value of 0.63 and champion value of 0.69, which is particularly impressive given that there is no EBL and the perovskite film has a high density of pinholes (Figure 2e). Furthermore, whilst CsSnI₃ films with 10 mol% SnCl₂ prepared from 8 wt% solution have a much greater density of pinholes than those prepared from 16 wt% solution (Supplementary Figure 8), the device *FF* is improved (Supplementary Figure 9 and Supplementary Table 6), consistent with the SnCl₂ preventing electrons moving from the PC₆₁BM into the ITO electrode.

The simplest possible explanation for the improved device performance with SnCl₂ additive is that the SnCl₂ forms a > 1 nm thick hole-selective layer at the ITO|CsSnI₃ interface. However, ultra-violet photoelectron spectroscopy (UPS) measurements

(Supplementary Figure 10 a&b) show that the valence band of SnCl₂ is 6.6 ± 0.1 eV below the vacuum level, which is well below that measured for CsSnI₃ at $4.9 \text{ eV} \pm 0.1 \text{ eV}$ (Supplementary Figure 11), in close agreement with that reported by Chung *et al.*³⁰. Consequently, a SnCl₂ layer at this interface with a thickness > 1 nm would be expected to impede rather than facilitate hole-extraction, thereby degrading device *FF* - which is not observed. Alternatively, it is possible that a layer of SnCl₂ with a thickness ≤ 1 nm is buried at the ITO|CsSnI₃ interface which, whilst sufficiently thin to be transparent to the flow of charge carriers, could perturb the interfacial energetics by modifying the surface potential at the ITO electrode. To explore this possibility, measurements of the work function of the ITO electrode were made using a Kelvin probe before and after deposition of SnCl₂ from a DMF solution having the same SnCl₂ loading as used to achieve 10 mol% SnCl₂ in a 8 wt% CsSnI₃ solution: 2.4 mg ml^{-1} SnCl₂. The work function of ITO treated with DMF only was measured to be 4.76 ± 0.06 eV. Following treated with 2.4 mg ml^{-1} SnCl₂ solution the work function is essentially unchanged at $4.72 \text{ eV} \pm 0.08 \text{ eV}$, which is a strong indication that the energetics for hole-extraction are neither improved nor degraded when SnCl₂ is added to the CsSnI₃ layer at the loading used.

A more likely explanation for the improvement in device performance is that the excess SnCl₂ at the surface of the CsSnI₃ crystallites moderately *n*-dopes the fullerene layer, forming a Schottky barrier to the unwanted extraction of electrons from the fullerene into the ITO electrode at the site of pinholes in the perovskite film, thereby allowing the devices to function well without the need for a EBL. The dark current-voltage characteristics re-plotted on a log-linear scale (Supplementary Figure 12) validate this conclusion, since the current in reverse bias is dramatically reduced with the SnCl₂ additive; by ~ 10 times at a bias of -1 V. This interpretation requires that the SnCl₂ at least partially diffuses into the fullerene layer and that there is an electron donating interaction from the SnCl₂ to the fullerene, giving rise to an *n*-type doping effect. To confirm this hypothesis UPS measurements were performed on a ~ 40 nm thick PC₆₁BM film spin cast onto a gold substrate pre-coated with a very thin ($<$

3 nm) film of SnCl_2 . The results of these measurements are summarised in Figure 6, from which it is evident that the energy difference between the Fermi level (E_f) and valence band (HOMO) edge increases by 240 meV when SnCl_2 is at the buried interface, consistent with n -type doping. It is not possible to determine the dopant density very close to the interface and at the site of the pinholes in the CsSnI_3 film, although if the coverage of SnCl_2 over the surface of the CsSnI_3 crystallites is approximately even - as schematically depicted in Figure 2f - then the SnCl_2 dopant density will be highest at the site of the pinholes in the perovskite film.

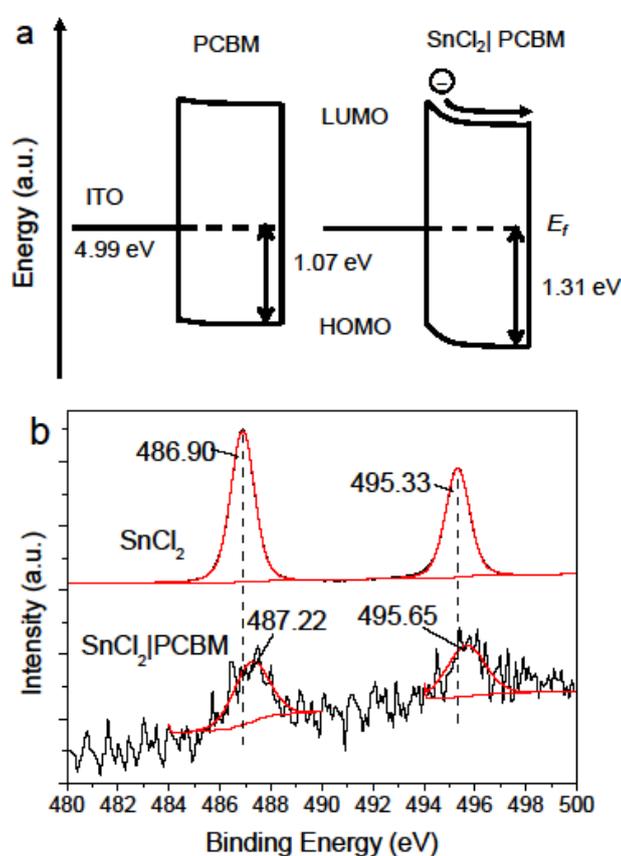

Figure 6 | Band diagrams depicting the energy level alignment at the ITO | PC_{61}BM interface and spectroscopic evidence for an n -type doping interaction. **a** Energy level diagram of an ITO| PC_{61}BM interface with and without SnCl_2 derived from the UPS data given in Supplementary Figure 10. The energy of the highest occupied molecular orbital (HOMO) and

lowest unoccupied molecular orbital (LUMO) for PC₆₁BM are depicted. The measured difference between the HOMO and Fermi level (E_f) in the PC₆₁BM with and without SnCl₂ doping: 1.31 eV and 1.07 eV respectively. **b** HRXPS spectra of the Sn 3d region from a thin film of SnCl₂ (labelled SnCl₂) and a film of PC₆₁BM doped with SnCl₂ (labelled SnCl₂|PC₆₁BM). The red lines correspond to curve fitting performed with CasaXPS (See Methods Section) and the vertical dashed grey lines are to guide the eye.

Consequently, the barrier to hole-extraction from the fullerene layer at the site of pinholes is likely to be considerably larger. Corroborating evidence for *n*-type doping is provided by HRXPS of the same films (Figure 6b), which shows that the binding energy of the Sn 3d orbitals in SnCl₂ is increased by 0.4-0.5 eV when incorporated in a PC₆₁BM film, consistent with partial electron transfer from the SnCl₂ to the PC₆₁BM. Based on a bandgap of 1.3 eV^{11,15,25} the energy of the conduction band edge of CsSnI₃ is 3.6 eV below the vacuum level, which is considerably shallower in energy than the LUMO of PC₆₁BM at 3.78 eV³¹ below the vacuum level, and so there is unlikely to be a barrier to electron extraction across this interface either with or without SnCl₂ doping of the PC₆₁BM layer.

Figure 7 shows the performance of CsSnI₃ PPV devices without encapsulation and tested in ambient air at a humidity of ~25% under constant 1 sun simulated solar illumination. After 45 minutes continuous illumination the device temperature stabilised at ~50 °C. To our knowledge the stability of these devices is the highest reported for any tin halide PPV to date: On average, η reduces to 70% of its starting value only after ~7 hours under continuous 1 sun illumination in ambient air, with the best performing devices taking 16 hours to reduce to the same value (Figure 7a)). The improvement in stability reported herein is a factor of 20 greater than devices with the same architecture fabricated using CH₃NH₃PbI_{3-x}Cl_x in place of CsSnI₃ fabricated in our laboratory, and 10-fold more stable than reported independently by the group of Zhang *et al.*²⁹, also for the same device architecture

(Figure 7a). Crucially this exceptional stability for a tin-perovskite PV is common to devices with and without metal halide additive, consistent with the dispersing of the SnCl_2 into the PCBM layer, and so is tentatively attributed to the removal of the EBL. However, champion stability is exhibited only by devices with a tin halide additive: 11 hours with no additive; 16 hours with 10 mol% SnCl_2 ; and 22 hours for SnI_2 . Crucially using SnCl_2 as an additive offers the advantage of the highest η , due to reduced sensitivity of device parameters to pin-holes, without complicating the process of device fabrication.

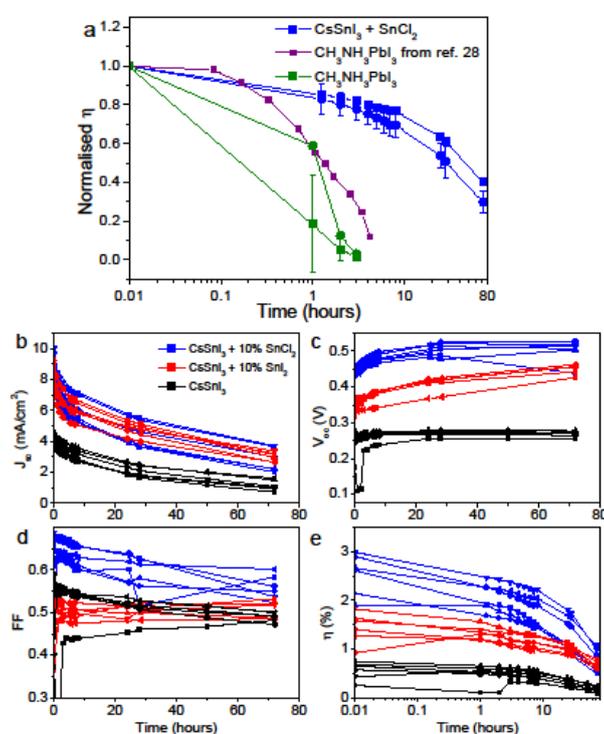

Figure 7 | PPV device stability tests under 1 sun constant illumination in ambient air for unencapsulated devices with the same architecture. **a** | Mean (squares) and champion (circles) normalised η for PPV devices *without encapsulation* tested in ambient air under continuous 1 sun simulated solar irradiation with the structure: (blue) ITO | $\text{CsSnI}_3 + 10$ mol% SnCl_2 | PC_{61}BM | BCP | Al at $\sim 25\%$ humidity and $\sim 50^\circ\text{C}$.; (green) ITO | $\text{CH}_3\text{NH}_3\text{PbI}_3$ | PC_{61}BM | BCP | Al at $\sim 25\%$ humidity and $\sim 50^\circ\text{C}$.; (purple) ITO | $\text{CH}_3\text{NH}_3\text{PbI}_3$ | PC_{61}BM | Bis-

C₆₀ | Ag reported in Ref. 29. Error bars are ± 1 standard deviation. A linear-linear plot of this data is also given in Supplementary Figure 13. **b-e** | Evolution of *JV* characteristics for a representative set of unencapsulated devices tested in air under continuous 1 sun simulated. The devices have the structure: ITO glass / CsSnI₃ + X / PC₆₁BM / BCP / Al, where X = 10 mol% SnCl₂ (blue), 10 mol% SnI₂ (red) or no additive (black). The temperature under the lamp stabilised at ~ 50 °C after 45 minutes continuous illumination. All curves are guides to the eye.

It is evident from Figure 7 (b-e) that most of the degradation in device η is due to loss in J_{sc} , whilst FF is very stable and V_{oc} actually increasing by $\sim 10\%$ for all devices. The increase in V_{oc} can be attributed to the improved crystallisation in the fullerene layer that occurs when the device is subject to intense light for an extended period, which reduces the number of LUMO tail states that erode V_{oc} ^{32,33} and/or partial oxidation of the electrode to form a very thin low work function aluminium oxide layer. The good stability in device FF indicates that the series resistance in these devices does not change significantly as the light harvesting ability deteriorates. This observation is consistent with the fact that Cs₂SnI₆ is a weak absorber of light and has a high electron mobility^{23,34}, and is compelling evidence that the barriers to electron transport across the CsSnI₃ / Cs₂SnI₆ and Cs₂SnI₆ / PC₆₁BM are small. That is, the Cs₂SnI₆ layer that forms at the CsSnI₃/fullerene interface as a result of air oxidation allows electron transport, whilst not significantly contributing to light harvesting.

The fact that devices with and without SnCl₂ have nearly comparable stability, in conjunction with evidence for *n*-type doping of the fullerene layer, indicates that in devices the SnCl₂ is no longer confined at the CsSnI₃ surface but is dispersed in the adjacent fullerene layer. Further evidence for this, and for a significant interaction between SnCl₂ and PC₆₁BM, is provided by the electronic absorption spectra shown in Supplementary Figure 14, which shows how the absorbance of a ~ 50 nm thick CsSnI₃ film prepared with 10 mol%

SnCl₂ at a wavelength of 450 nm changes with time exposed to ambient air, with and without a PC₆₁BM overlayer. It is evident that the CsSnI₃ with 10 mol% added SnCl₂ becomes less stable when buried beneath a layer of PC₆₁BM which is consistent with partial removal of the SnCl₂ from the perovskite surface. Conversely, Supplementary Figure 14b shows that washing with chlorobenzene has no detrimental effect on the perovskite film stability, which together is compelling evidence for a strong interaction between PC₆₁BM and SnCl₂. Notably, whilst the Al electrode is evidently able to slow the ingress of water and oxygen into the device sufficiently for a stability study on the time scale reported herein - consistent with lifetime studies of organic PV devices using a very similar HBL³⁵ – its long term barrier properties are limited.³⁵ It is anticipated that further significant improvements in device stability can be achieved by using an electron extracting electrode with better barrier properties towards ambient water and oxygen.

Discussion

Taken together the aforementioned experiments provide compelling evidence that SnCl₂ is the best of the tin halides investigated for the current application. The reason for this is almost certainly a complex interplay between a number of factors including the following: (i) Firstly, Cl cannot easily displace I in CsSnI₃ perovskite, due to the size mismatch of the two halides, and so SnCl₂ is pushed to the surface of the crystallites, whilst still ensuring that the perovskite is formed in a tin-rich environment.; (ii) SnCl₂ is much more soluble in common solvents, including DMF, than SnF₂ due to its greater covalency, which is particularly important when processing films from solution at room temperature, as in our fabrication method.; (iii) The propensity for solid-state diffusion of tin chloride into fullerene is likely to be larger due to the smaller size and lower mass of chloride species compared to the iodide and bromide analogues.

In summary, a strategy for fabricating CsSnI₃ based photovoltaic devices with the highest fill factor reported for a tin PPV has been described, that simultaneously removes the requirement for an electron blocking layer at the hole-extracting electrode and the need for an additional processing step to minimise the density of pinholes in the perovskite film. We have shown that the improved performance and tolerance to pin-holes in the perovskite film stems from *n*-doping of the fullerene electron-transport layer by SnCl₂, and that the stability of unencapsulated CsSnI₃ devices based on a simplified EBL free device architecture is improved by at least an order of magnitude as compared to lead based PPV with the same architecture when tested under continuous simulated solar illumination in ambient air at 50°C. Taken together, the findings reported herein justify an intensive research effort into tin perovskite PVs, focused on improving η to a level comparable to that of lead perovskite PVs.

Methods

Materials

CsI (Sigma-Aldrich 99.9%), SnI₂ (Alfa Aesar, 99.999%), SnCl₂ (Sigma Aldrich, 99.99%), SnF₂ (Acros Organics, 99%), SnBr₂ (Alfa Aesar, 99.4%), Perovskite Precursor Ink (for nitrogen processing) (Ossila, 1:1:4 PbCl₂:PbI₂:CH₃NH₃I, 99.999%:99.999%:99%, 99.8% DMF), PC₆₁BM (Solenne, 99.5%), bathocuproine (BCP) (Alfa Aesar, 98%), *N,N*-dimethylformamide (DMF) (VWR, anhydrous, 99.8%), chlorobenzene (Sigma-Aldrich, anhydrous, 99.8%), acetone (Sigma-Aldrich, GPR, 99%), propan-2-ol (Sigma-Aldrich, HPLC, 99.8%), deionised H₂O (purite dispenser, >10 MΩ). CsI and non-anhydrous solvents were stored in air. All other chemicals were stored in a nitrogen filled glove box (<5 ppm O₂ and <1 ppm H₂O).

B- γ CsSnI₃ films

In a dry nitrogen filled glovebox CsI, SnI₂ and tin(II) halide were mixed together in 1:1:0.1 molar ratio. To this mixture *N,N*-dimethylformamide (DMF) was added to make an 8 wt.% solution (total mass of solids), which was stirred overnight before use. To deposit films, two drops of solution were cast onto a substrate spinning at 4000 rpm for 60 seconds. The B- γ phase forms immediately upon solvent evaporation.

Device fabrication

Indium tin oxide (ITO) coated glass slides (Thin Films Devices Inc. $15 \pm 3 \Omega/\text{sq.}$) were held in vertical slide holders and ultra-sonically agitated in an acetone bath, followed by a high purity water bath with a few drops of surfactant, followed by high purity deionized water only bath, and finally an isopropanol bath. After this, the slides were suspended in hot acetone vapour for 10 seconds before UV/O₃ treatment for 15 minutes.

Immediately after UV/O₃ treatment the slides were transferred into a dry nitrogen filled glovebox for CsSnI₃ film deposition, followed by deposition of a PC₆₁BM film from 15 mg/ml chlorobenzene solution using a spin speed of 1500 rpm. The substrates were then loaded into a high vacuum thermal evaporator located in the same glovebox and 6 nm of bathocuproine (BCP) was deposited followed by 50 nm of Al at a pressure of 1×10^{-5} mbar (with substrate rotation). The Al electrode was deposited through a shadow mask to make six devices per slide, each with an area of 6 mm².

Device Testing

Device testing was performed in the same glove box as used for device fabrication or, as for the stability testing, using a solar simulator outside the glove box. Current density–voltage (*JV*) curves were measured using a Keithley 2400 source-meter under AM1.5G solar illumination at 100 mW/cm² (1 sun), scanned from -1 V to +1 V at 0.1 V/s. Devices exhibited no significant hysteresis (Figure S6). External quantum efficiency (EQE) measurements

were carried out using a Sciencetech SF150 xenon arc lamp and a PTI monochromator, with the monochromatic light intensity calibrated using a Si photodiode (Newport 818-UV). The incoming monochromatic light was chopped at 180 Hz. For signal measurement a Stanford Research Systems SR 830 lock-in amplifier was used.

X-ray Diffraction (XRD)

XRD was performed on thin films of CsSnI₃ prepared from 16 wt.% (total solids) DMF solution deposited onto a substrate spinning at 4000 rpm for 60 seconds. A thicker film than used in the devices was used here to obtain sufficient signal for the time dependent studies. Scans were recorded under a flow of gas (dry nitrogen, dry air, humid nitrogen or ambient air) using a Cu K $\alpha_{1/2}$ source in θ - θ mode on a Bruker D8 Advance powder diffractometer equipped with an Anton-Paar HTK900 gas chamber. Humid nitrogen was introduced by bubbling through water before the chamber. The measured XRD patterns were corrected for height offset (due to the thickness of the film) by calibrating the 2θ scale with reference the expected peak positions for pure B- γ CsSnI₃. Simulated diffraction patterns were calculated using the program Mercury 3.1 using CIFs from the Inorganic Crystal Structure Database (ICSD).

X-ray / Ultraviolet Photoelectron Spectroscopy

XPS was performed on film on gold coated glass substrates using a Kratos AXIS Ultra DLD. Samples were unavoidably exposed to air for approximately 1 minute during transfer from an air tight box to the vacuum chamber of the instrument. XPS measurements were carried out in a UHV system with a base pressure of 5×10^{-11} mbar. The sample was excited with X-rays from a mono-chromated Al K α source ($h\nu = 1486.7$ eV) with the photoelectrons being detected at a 90° take-off angle. The sputtering was carried out at room temperature using a Minibeam I ion gun (Kratos Analytical, UK). A beam of 4 keV Ar⁺ ions were incident on a 3 × 3 mm area of the sample surface. Curve fitting was performed using the CasaXPS package, incorporating Voigt (mixed Gaussian-Lorentzian) line shapes and a Shirley background.

UPS was performed in the same vacuum system as for XPS using a He 1 α source at 21.22 eV.

Electronic Absorption Spectroscopy

UV/Vis/NIR spectra were measured for optically thin films of CsSnI₃ on glass or ITO substrates. Experiments from the same set were performed on the same day.

Contact potential measurement

Work function measurements were performed using a Kelvin probe referenced to freshly cleaved highly oriented pyrolytic graphite in a nitrogen-filled glove box co-located with the spin coater and thermal evaporator.
