Abstract

Transition metal sulfides have been suggested as promising materials for efficient energy storage with superior electrochemical performances. Compound NiMoS\textsubscript{4}-A was synthesized by a facile chemical co-precipitation process, followed by calcining at 450 °C in Ar. The as-prepared NiMoS\textsubscript{4}-A electrode exhibits a high specific capacity of 313 C g\textsuperscript{-1} at 1 A g\textsuperscript{-1} and good rate capability (83% retention at 10 A g\textsuperscript{-1}). Electrochemical impedance spectroscopy (EIS) results indicate that the good performances could be attributed to the low internal and charge transfer resistances. Additionally, the quantitative charge storage analysis reveals that the Faradaic redox process dominates at lower scan rates (78% at 1 mV s\textsuperscript{-1}), while the capacitive effect dominates at higher scan rates (56% at 20 mV s\textsuperscript{-1}). Furthermore, a hybrid supercapacitor (HSC), with NiMoS\textsubscript{4}-A as the positive electrode and activated carbon (AC) as the negative electrode, displays a high energy density of 35 Wh kg\textsuperscript{-1} at an average power density of 400 W kg\textsuperscript{-1}. Meanwhile, the HSC exhibits excellent cycle stability, maintaining 82% of the initial capacitance after 10000 charge-discharge cycles even at a high current density of 5 A g\textsuperscript{-1}. These good electrochemical performances indicate that NiMoS\textsubscript{4}-A is a promising positive electrode material for hybrid supercapacitors.
1. Introduction

The demand for high-performance electrochemical energy storage devices is ever-growing as they are critical components for portable electronics, electric vehicles, and an efficient storage medium for energy from renewable sources.\(^1\) Rechargeable batteries are considered as a promising technology which can meet these requirements.\(^2,3\) However, batteries often offer low charge/discharge rate and power density which is insufficient when a short-burst of peak power is needed.\(^4\) To solve this problem, researchers have shown a tremendous amount of interest on electrochemical supercapacitors owning to their high powder density, rapid charge-discharge rate and outstanding cycle life.\(^5-7\) According to the charge storage mechanisms, the supercapacitor can be classified into two types: electrical double-layer capacitors (EDLCs) and pseudocapacitors.\(^8\) EDLCs store charges via reversible adsorption/desorption of cations and anions at the electrode/electrolyte interface while pseudocapacitors store charges through fast Faradic reactions at the electrode surface.\(^9\) Currently, most commercial supercapacitors are EDLCs which possess better performance in terms of cycle life and power density, but the low specific capacitance and energy density limit their widespread applications.\(^10\) On the basis of these circumstances, it is supposed that developing hybrid supercapacitors (HSCs) could be a promising approach to fulfill the high energy density without sacrificing the power density and cycle life.\(^11\) HSCs are usually composed of one battery-type electrode and one capacitive electrode, which could combine advantages of batteries and supercapacitors, delivering enhanced capacitance and high energy density.\(^1,8\)

Transition metal oxides are the most common battery or pseudocapacitive materials and have been extensively studied due to their high theoretical capacities and low cost.\(^7\) Many materials have been claimed holding good supercapacitor performances such as MnO\(_2\),\(^12,13\) NiO,\(^14,15\) MoO\(_3\),\(^16,17\) etc. However, the performances of metal oxides often suffer from poor conductivity and mechanical stability especially under high rates.\(^18\) It is known that the metal
sulfides usually possess higher conductivity than the corresponding oxides. Therefore, plenty of sulfides have been applied as new pseudocapacitive materials with good performances being obtained. For instance, Pang et al. prepared a NiS$_2$ nanocube electrode via a microwave-assisted method, demonstrating a large specific capacitance of 695 F g$^{-1}$ at 1.25 A g$^{-1}$ and an excellent cycling performance with 93.4% retention after 3000 cycles.\textsuperscript{19} Acerce et al.’s research indicates that chemically exfoliated nanosheets of MoS$_2$ can efficiently intercalate H$^+$, Li$^+$, Na$^+$ and K$^+$ ions to achieve high capacitance in a variety of aqueous electrolytes.\textsuperscript{20} As NiMoO$_4$ has been confirmed as a good capacitive material,\textsuperscript{21, 22} it can be deduced that, its sulfide analogue, NiMoS$_4$ would also be a good candidate for supercapacitors. NiMoS$_4$ has been applied in hydrogen evolution\textsuperscript{23} and dye-sensitized solar cells\textsuperscript{24} as previously reported.

Herein, we report a ternary compound NiMoS$_4$-A which was synthesized by a facile chemical co-precipitation process followed by calcining at 450 °C in Ar. Physical and electrochemical properties of the NiMoS$_4$-A were extensively studied. The NiMoS$_4$-A electrode exhibits a high specific capacity of 313 C g$^{-1}$ at 1 A g$^{-1}$ and a good rate capability (83% retention at 10 A g$^{-1}$). Electrochemical impedance spectroscopy (EIS) results indicate that the good performances could be attributed to the low internal and charge transfer resistances. Moreover, a hybrid supercapacitor (HSC), with NiMoS$_4$-A as the positive electrode and activated carbon (AC) as the negative electrode, was fabricated to investigate the performances in practical energy storage devices. The HSC displays a high energy density of 35 Wh kg$^{-1}$ at an average power density of 400 W kg$^{-1}$. Meanwhile, an excellent cycle stability is achieved: 82% of the initial capacitance is retained after 10000 charge-discharge cycles even at a high current density of 5 A g$^{-1}$. These results indicate that NiMoS$_4$-A is a promising electrode material for high energy storage devices.
2. Experimental

2.1. Synthesis of (NH$_4$)$_2$MoS$_4$

(NH$_4$)$_2$MoS$_4$ was synthesized following a previously reported method.$^{23}$ To prepare the (NH$_4$)$_2$MoS$_4$, 7.5 g (NH$_4$)$_6$Mo$_7$O$_{24}$·4H$_2$O was dissolved in 5 mL ammonia and 10 mL H$_2$O under constant stirring. Then 60 mL of 20% (NH$_4$)$_2$S solution was added dropwise at room temperature. The system was kept in a water bath at 60 °C for 2 h. After that, the obtained red-brown solution was cooled in an ice-bath to allow the (NH$_4$)$_2$MoS$_4$ to crystallize. Finally, the resultant crystals were collected by centrifugation and washed with ethanol several times. The products were dried under vacuum at 30 °C. The mechanism of formation of the (NH$_4$)$_2$MoS$_4$ crystal can be expressed in the equations:$^{25}$

\[
(NH_4)_6Mo_6O_{24} + 8NH_3 \cdot H_2O \rightarrow 7(NH_4)_2MoO_4 + 4H_2O \tag{1}
\]

\[
(NH_4)_2MoO_4 + 4(NH_4)_2S + 4H_2O \rightarrow (NH_4)_2MoS_4 + 8NH_3 \cdot H_2O \tag{2}
\]

2.2. Synthesis of NiMoS$_4$

Firstly, 4 mmol (NH$_4$)$_2$MoS$_4$ was dispersed in 30 mL water with 5 mL ethanol. Similarly, 4 mmol Ni(NO$_3$)$_2$·6H$_2$O was dissolved in 30 mL water with 5 mL ethanol. The Ni(NO$_3$)$_2$ solution was added into the (NH$_4$)$_2$MoS$_4$ solution under vigorous magnetic stirring and kept overnight. The black precipitate was collected by centrifugation, washed with distilled water and absolute ethanol several times, and finally vacuum dried at 30 °C. In addition, the NiMoS$_4$ was further calcined at 450 °C for 2 h under Ar atmosphere. For comparison, the calcined NiMoS$_4$ was denoted as NiMoS$_4$-A.

2.3. Material Characterizations

*Physical Characterization*
X-ray Diffraction (XRD) patterns were obtained on a Panalytical X’Pert Pro Multi-Purpose Diffractometer (MPD) with Cu Kalphal radiation working at 45 kV and 40 mA. The morphologies and microstructures of the as-synthesized materials were identified using scanning electron microscopy (SEM) (ZEISS SUPRA 55-VP). The elemental compositions were investigated by Energy-dispersive X-ray spectroscopy studies (EDX) attached to the SEM.

**Electrochemical measurements**

The working electrode was prepared as follows: an homogeneous slurry comprised of the active materials, acetylene black and polytetrafluoroethylene (PTFE) in a mass ratio of 8 : 1 : 1 was coated onto Ni foam (1 × 1 cm²), pressed at 10 MPa, and finally dried at 60 °C under vacuum. The mass loading of the active materials on each working electrode was 1-2 mg cm⁻². The performance of the prepared working electrode was firstly investigated in a three-electrode system with a piece of Pt mesh (1 × 1 cm²) and an Ag/AgCl electrode (sat. KCl) serving as counter and reference electrodes, respectively. Hybrid supercapacitors were also fabricated using the as-prepared working electrode as the positive electrode and an activated carbon (AC) electrode as the negative electrode. The electrochemical measurements including cyclic voltammetry (CV), galvanostatic charge–discharge (GCD) and electrochemical impedance spectroscopy (EIS) were carried out on a Solartron 1470E/1455 multichannel cell test system. Impedance spectroscopy were recorded with a potential amplitude of 5 mV at open circuit potential. All the measurements were performed at room temperature in 2 M KOH aqueous solution as electrolyte.

2.4. Calculations

The specific capacity of the electrode can be calculated from CV curves by the equation:²⁶,

\[
C_p = \frac{1}{2mv} \int I(V) dV
\]  

(3)
where \( C_p \) is the specific capacity (C g\(^{-1}\)), \( m \) is the mass the active materials (g), \( v \) is the scan rate (V s\(^{-1}\)), \( I \) is the current at V (A) and \( dV \) is the differential potential.

The specific capacity could also be determined from the galvanostatic charge-discharge curves according to the following equation:\(^{28, 29}\)

\[
C_p = \frac{I \times \Delta t}{m} \tag{4}
\]

where \( C_p \) is the specific capacity (C g\(^{-1}\)), \( I \) is the constant discharge current (A), \( \Delta t \) is the discharge time (s), \( m \) is the mass the active materials (g).

In order to achieve high electrochemical performance of the hybrid supercapacitor (HSC), the mass ratio between the positive and negative electrodes was optimized by balancing the charge stored at the electrodes. The charge stored by electrode can be obtained by the equation:\(^{26, 30}\)

\[
q = C_p \times m \tag{5}
\]

where \( C_p \) is the specific capacity (C g\(^{-1}\)), \( m \) is the mass of the active materials (g). According to equation (5) and \( q_+ = q_- \), the mass ratio of active materials on the positive and negative electrode in a hybrid supercapacitor can be calculated:\(^{31}\)

\[
\frac{m_+}{m_-} = \frac{C_-}{C_+} \tag{6}
\]

Since the HSC performed quasi rectangular CV curves, the specific capacitance could be calculated as:\(^{28, 29}\)

\[
C_s = \frac{I \times \Delta t}{m \times \Delta V} \tag{7}
\]

where \( C_s \) is the specific capacitance (F g\(^{-1}\)), \( I \) is the constant discharge current (A), \( \Delta t \) is the discharge time (s), \( m \) is the total mass of the active materials on both the positive and negative electrode (g), and \( \Delta V \) is the potential change excluding the IR drop in the discharge step (V).
The energy densities and corresponding power densities of the HSC were obtained from the following equations:22,32

\[
E = \frac{C_s V^2}{2 \times 3.6} \quad (8)
\]

\[
P = \frac{E \times 3600}{\Delta t} \quad (9)
\]

where \(E\) is the energy density (Wh kg\(^{-1}\)), \(C_s\) is the specific capacitance (F g\(^{-1}\)), \(V\) is the capacitor potential window excluding the IR drop (V), \(P\) is the power density (W kg\(^{-1}\)), and \(\Delta t\) is the discharge time (s).

3. Results and Discussion

The compositions of the synthesized \((\text{NH}_4)_2\text{MoS}_4\) and \(\text{NiMoS}_4\) were examined by X-ray Diffraction (XRD). As shown in Figure 1a, the diffraction peaks of the as-prepared \((\text{NH}_4)_2\text{MoS}_4\) matched well with the orthorhombic \((\text{NH}_4)_2\text{MoS}_4\) (ICCD 00-048-1662), specifically, the major peaks at around 14.6°, 17.3°, 18.5°, 29.1° and 37.5° can be indexed to the crystal planes (011) (111) (200) (040) and (400) respectively. These results indicate that the \((\text{NH}_4)_2\text{MoS}_4\) was successfully prepared. \(\text{NiMoS}_4\) was obtained by reacting \((\text{NH}_4)_2\text{MoS}_4\) with nickel nitrate. No peaks were found on the XRD patterns of \(\text{NiMoS}_4\) (Figure 1b), showing typical amorphous features, which is consistent with the results reported in the literature.23 As the \(\text{NiMoS}_4\) was further calcined at 450 °C, obvious diffraction peaks appeared on the \(\text{NiMoS}_4\)-A patterns (Figure 1b). The peaks at 14.2°, 33.0° and 58.4° could be assigned to the (003) (101) and (110) planes of \(\text{MoS}_2\) (ICDD 04-008-2233) while the peaks at 31.4°, 35.3°, 38.8°, 45.1°, 53.4° and 60.9° corresponded to the (200) (210) (211) (220) (311) and (321) planes of \(\text{NiS}_2\) (ICCD 04-003-1992). The results reveal that the \(\text{NiMoS}_4\)-A sample contains small quantities of poorly crystallized \(\text{NiS}_2\) and \(\text{MoS}_2\).

To investigate morphology properties of the synthesized materials, scanning electron microscopy (SEM) was carried out for \(\text{NiMoS}_4\) and \(\text{NiMoS}_4\)-A. As shown in Figure 2a and b,
NiMoS$_4$ is composed of irregular particles. For NiMoS$_4$-A (Figure 2c and d), the particles are loosely agglomerated forming porous structures, which could improve the access of the electrolyte into the material during charge-discharge, thus promoting energy storage performances. Energy-dispersive X-ray spectroscopy studies (EDX) were conducted to determine the element compositions in the samples. Elements Ni, Mo, and S are observed in NiMoS$_4$ according to the EDX spectrum (Figure 3a), which is in agreement with the reagents used during the preparation processes. The distribution of each element was identified through elemental mapping as shown in Figure 3b. Clearly, the Ni, Mo, and S elements are uniformly distributed, the same result was also found for the NiMoS$_4$-A sample (Figure S1), indicating that possible agglomeration of the segregated NiS$_2$ and MoS$_2$ is not significant.

The prepared electrodes were examined in a three-electrode system using a 2M KOH electrolyte in order to explore the electrochemical properties. Figure 4a indicates the cyclic voltammetry (CV) curves of NiMoS$_4$ at different scan rate from 1 to 20 mV s$^{-1}$ in a potential window of 0 to 0.5 V vs. Ag/AgCl. Redox peaks are found in the CV curves, demonstrating that the energy storage ability is mainly contributed by the Faradaic redox reactions. It can be clearly seen that the CV curves exhibit a similar shape over all the scans, indicating good kinetic reversibility of the NiMoS$_4$ electrode. Moreover, it can be deduced that the electrode presents low polarization and rapid electronic and ionic transportation since the anodic and cathodic peaks slightly shift towards the positive and negative potentials respectively at increasing scan rates. The CV curves of NiMoS$_4$-A at different scan rates are presented in Figure 4b. It is evident that CV behaviors similar to that of NiMoS$_4$ were observed. However, sample NiMoS$_4$-A exhibits larger current density responses than NiMoS$_4$ at same scan rate. Figure 4c displays the CV plots of NiMoS$_4$ and NiMoS$_4$-A at 10 mV s$^{-1}$, it is believed that the integral area of CV curves is proportional to the specific capacity. Obviously, the CV curves of NiMoS$_4$-A enclose a larger area than that of NiMoS$_4$, suggesting that a larger number
charges can be stored in the NiMoS$_4$-A electrode. The specific capacities of NiMoS$_4$ and NiMoS$_4$-A calculated based on the corresponding CV curves at different scan rates are shown in Figure 4d. The specific capacity of NiMoS$_4$-A is 353.4 C g$^{-1}$ at 1 mV s$^{-1}$, larger than the value for NiMoS$_4$ (286.8 C g$^{-1}$). All the capacities experience gradual decrease with increasing scan rate, reaching 231.5 C g$^{-1}$ and 166.2 C g$^{-1}$ at 20 mV s$^{-1}$ for NiMoS$_4$-A and NiMoS$_4$ respectively. It can be seen that the NiMoS$_4$-A performs better in terms of rate capability than NiMoS$_4$, namely, retaining 65.5% vs. 57.9% from 1 to 20 mV s$^{-1}$.

Galvanostatic charge–discharge (GCD) measurements for NiMoS$_4$ and NiMoS$_4$-A with current densities ranging from 1 to 10 A g$^{-1}$ are recorded in Figure 5a and b respectively. It can be seen that both NiMoS$_4$ and NiMoS$_4$-A exhibit nonlinear charge–discharge GCD curves, which further support the Faradaic behaviors of these materials. Figure 5d compares GCD curves of NiMoS$_4$ and NiMoS$_4$-A at a current density of 1 A g$^{-1}$. It shows that more charge can be stored on the NiMoS$_4$-A electrode due to its longer discharge time, which is consistent with the above CV results. The specific capacities calculated based on the GCD curves are shown in Figure 5d. NiMoS$_4$-A exhibits a good specific capacity of 313 C g$^{-1}$ at a current density of 1 A g$^{-1}$. At current densities of 2, 4, 6, 8, and 10 A g$^{-1}$, the specific capacities are 295, 274.4, 265.2, 256, and 248 C g$^{-1}$ respectively. This means that roughly 83% of the capacity can be maintained with a 10-fold increase in the current density, implying an excellent rate capability of the NiMoS$_4$-A sample. The gradual decrease in specific capacity could be ascribed to insufficient active materials involved in the redox reaction as diffusion time is limited for electrolyte ions accessing the active materials at high charge-discharge rates. Noticeably, sample NiMoS$_4$-A has a superior specific capacity to that of sample NiMoS$_4$, specifically, only 221 C g$^{-1}$ is achieved by NiMoS$_4$ at 1 A g$^{-1}$ and 67% of the initial value is preserved when the current increases to 10 A g$^{-1}$.
The differences of electrochemical performance between samples NiMoS₄ and NiMoS₄-A are partially related to the impedance of the electrode. Therefore, electrochemical impedance spectroscopy (EIS) was carried out to further explore charge-transfer kinetics. Figure 5e depicts the Nyquist plots of NiMoS₄ and NiMoS₄-A at open circuit potential. It is evident that the graph is composed of a semicircle in high frequency region and a linear part in low frequency region. An equivalent circuit for fitting the Nyquist plots is shown in Figure 5f, where $R_s$ is the internal resistance, which is also known as equivalent series resistance (ESR), $R_{ct}$ is the charge transfer resistance, $W_0$ is the Warburg impedance, $C_{dl}$ is the electric double layer capacitance, $C_p$ is the faradaic capacity, and $R_L$ is the leakage resistance. The fitting curve and the experimental data match very well with each other (Figure S2), confirming that the proposed equivalent circuit model is suitable for the electrode. The internal resistance ($R_s$), containing the bulk resistance of the electrolyte, the intrinsic resistance of the active materials and the contact resistance from the interface of active material and current collector, could be estimated by the intersection of the curves on the real axis. The $R_s$ for NiMoS₄-A is 0.53 Ω, slightly lower than 0.62 Ω for NiMoS₄, suggesting that the NiMoS₄-A possesses higher conductivity. The $R_{ct}$, demonstrating the rate of Faradaic redox process at the electrode-electrolyte interface, can be evaluated by the diameter of the semicircle. Sample NiMoS₄-A exhibits smaller $R_{ct}$ (1.9 Ω) than that for sample NiMoS₄ (3.2 Ω), implying the faster electron transfer on the NiMoS₄-A electrode, possibly owning to the porous morphology of NiMoS₄-A, which could facilitate the diffusion of electrolyte into the active materials, thus lowering the charge resistance. The straight line at low frequencies is associated with the Warburg impedance ($W_0$), which is supposed to describe the diffusive resistance of electrolyte ions within the electrode. Sample NiMoS₄-A exhibits a more vertical line, showing lower mass-transfer resistance in the host materials. Overall, the better impedance performances in terms of $R_s$, $R_{ct}$ and $W_0$ for NiMoS₄-A...
A should lead to improved electrochemical properties, which has been confirmed by the previous CV and GCD results.

Normally, the total charge stored in the electrode is contributed by two different processes: the surface capacitive process and the diffusion controlled Faradaic effect. CV data could provide the insight into the charge storage mechanism based on the following equation\textsuperscript{42,43}: 

\[ i = a v^b \]  

(9)

Where \( i \) is the measured current response, \( v \) is the scan rate, and \( a \) and \( b \) are adjustable parameters. In the condition of \( b = 1 \), the current indicates the surface capacitive component, while when \( b = 0.5 \), the current represents the diffusion controlled Faradaic component. Therefore, the total current at a fixed potential can be expresses as:\textsuperscript{42,44}

\[ i = k_1 v + k_2 v^{1/2} \]  

(10)

where \( k_1 v \) and \( k_2 v^{1/2} \) correspond to the current contribution by surface capacitive process and the diffusion controlled Faradaic effect, respectively. For analytical purpose, we rearrange the equation to

\[ i/v^{1/2} = k_1 v^{1/2} + k_2 \]  

(11)

By plotting the \( i/v^{1/2} \) vs. \( v^{1/2} \) at different potentials, the values of \( k_1 \) (slope) and \( k_2 \) (intercept) could be determined, thus the specific current contribution at each potential could be obtained. Finally, the fraction of the charge stored from capacitive effect and diffusion-controlled Faradaic process could be extracted quantitatively by integrating the CV area. In Figure 6a, the current response of diffusion controlled process (blue area) on the NiMoS\textsubscript{4}-A electrode is compared with total current at a scan are of 5 mV s\textsuperscript{-1}. The diffusion controlled process occupies around 61% of the total charge storage and the remaining portion is originated from the surface capacitive effect. Based on the same approach, the percentages of diffusion controlled process on NiMoS\textsubscript{4} and NiMoS\textsubscript{4}-A electrodes at various scan rate are compared in Figure 6b. The two materials present quite similar trends, namely, the diffusion controlled process contribution
gradually decreases with increase in scan rate, reaching around 40% at a scan rate of 20 mV s\(^{-1}\). In other words, the Faradaic redox process dominates at lower scan rates while the capacitive effect matters at higher scan rates. However, at each specific scan rate, the percentage of diffusion controlled process is slightly higher on the sample NiMoS\(_4\)-A than that on the sample NiMoS\(_4\), suggesting easier redox reactions on the NiMoS\(_4\)-A electrode, which is well in accordance with the impedance results.

Clearly, as an energy storage material, the electrochemical performance of NiMoS\(_4\)-A is superior than that of NiMoS\(_4\), which could be related to the heating process. XRD shows that weak peaks of NiS\(_2\) and MoS\(_2\) appear after heating in Ar. It is supposed that the interaction between the MoS\(_2\) and NiS\(_2\) components could promote the activity and improve its conductivity.\(^{23}\) Our impedance results have also confirmed the lower resistance of NiMoS\(_4\)-A. Therefore, it can be concluded that the synergistic effect between the small amount of MoS\(_2\) and NiS\(_2\) in sample NiMoS\(_4\)-A improves the electrochemical performance of the electrode, resulting in a higher specific capacity of the NiMoS\(_4\)-A than that of the NiMoS\(_4\).

To further explore the electrochemical properties of the NiMoS\(_4\)-A electrode in a practical energy storage device, a hybrid supercapacitor (HSC) was fabricated using NiMoS\(_4\)-A as the positive electrode and activated carbon (AC) as the negative electrode. The AC electrode performs a typical feature of EDLC (Figure S3). Figure 7a demonstrates the CV curves of NiMoS\(_4\)-A//AC HSC with different voltages ranging from 1.0 to 1.7 V at a scan rate of 5 mV s\(^{-1}\). Obviously, the HSC has a stable performance with voltages up to 1.6 V, however when the voltage extends to 1.7 V a polarization curve appears with a much higher current response, suggesting that a severe side reaction of water electrolysis is taking place. Consequently, the operating voltage window for the HSC is selected as 0 to 1.6 V. The CV curves of the HSC at various scan rates are shown in Figure 7b. The quasi-rectangular CV shape at all scans reveals that the energy stored in this HSC originates from hybrid effects of the electric double-layer
and Faradaic redox effects, this is further confirmed by the GCD curves (Figure 7c). The lower the current densities, the more obviously non-linear the charge-discharge curves are. The specific capacitances of the HSC based on Equation 7 are calculated in Figure 7d. There is a significant decrease from 0.5 to 2 A g\(^{-1}\), but from 2 to 20 A g\(^{-1}\), the values remains stable, indicating a good rate capability. Specifically, 101.3, 84.6, 73.1, 67.1, 63.8, 60.5, and 59.1 F g\(^{-1}\) are achieved at current density of 0.5, 1, 2, 5, 10, 15, and 20 A g\(^{-1}\) respectively (Figure 7d), higher than those of other similar HSCs, such as CoMoS\(_4\)/rGO (77 F g\(^{-1}\) at 0.5 A g\(^{-1}\))\(^{45}\) and NiMoO\(_4\)/rGO//N-doped graphene (84 F g\(^{-1}\) at 0.5 A g\(^{-1}\))\(^{36}\). The durability of the HSC was evaluated over 10000 cycles at a current density of 5 A g\(^{-1}\) (Figure 7e). As seen from the graph, about 8% of the initial capacitance is lost during the first 200 cycles, after that, the value remains almost constant, showing an overall capacitance retention of 82% after 10000 cycles. The impedance spectra before and after the cyclic test is shown in the inset of Figure 7e. The R\(_s\) is nearly unchanged and the R\(_ct\) increases by about only 0.6 Ω after the 10000 cycle test, confirming the outstanding stability. The first and last ten cycles of the GCD curves are presented in Figure S4. The excellent electrochemical stability could be attributed to the structural features of the materials. In particular, the effective interfacial area between the active materials and the electrolyte could facilitate the electrolyte accessing the active sites. Moreover, the porous structure could buffer the volume change during rapid charge-discharge process and prevent structural collapse.

Specific energy and power densities are two key parameters to investigate in an electrochemical energy storage device.\(^{19}\) The Ragone plots of the HSC are displayed in Figure 7f. The obtainable highest energy density is 35 Wh kg\(^{-1}\) at a power density of 400 W kg\(^{-1}\), which is comparable to those of previously reported devices, such as Co\(_9\)S\(_8\) nanoflakes//AC (31.4 Wh kg\(^{-1}\) at 200 W kg\(^{-1}\))\(^{41}\), CoMoS\(_4\)/rGO (27.2 Wh kg\(^{-1}\) at 400 W kg\(^{-1}\))\(^{45}\) and CoMoO\(_4\)-graphene//AC (21.1 Wh kg\(^{-1}\) at 300 W kg\(^{-1}\))\(^{46}\). The high energy density should benefit from the
high capacitance of NiMoS₄-A electrode. The HSC still delivers an energy density of 13.5 Wh kg⁻¹ at a very high power density around 13000 W kg⁻¹.

4. Conclusion

We have synthesized NiMoS₄-A through a facile chemical co-precipitation process followed by calcining at 450 °C. The NiMoS₄-A electrode performs with a good specific capacity of 313 C g⁻¹ at 1 A g⁻¹ while still maintaining 83% at 10 A g⁻¹ in a KOH electrolyte. The detailed charge storage mechanism analysis reveals that surface capacitive process and diffusion controlled Faradaic reaction contribute together to the energy storage, and that the Faradaic redox process dominates at lower scan rates (78% at 1 mV s⁻¹) while the capacitive effect matters at higher scan rate (56% 20 mV s⁻¹). Furthermore, a hybrid supercapacitor (HSC) was fabricated using NiMoS₄-A as the positive electrode and activated carbon (AC) as the negative electrode. The HSC delivers 1.6 V cell voltage and 35 Wh kg⁻¹ energy density at a power density of 400 W kg⁻¹. Additionally, the HSC exhibits good cycle stability, retaining 82% of the initial capacitance after 10000 charge-discharge cycles even at a high current density of 5 A g⁻¹. These good electrochemical performances indicate the great potential of NiMoS₄-A for hybrid supercapacitors.
