Abstract—Much of computer science involves problems where it is considered to be easier to check that an answer is correct than to find a correct answer (the complexity class NP). In this talk, we outline results that apply this notion to checking outsourced computations for data analytics.

I. BACKGROUND

The increasing popularity of data analytics means dramatic increases in scale: much larger models with many parameters to set optimally, and much larger training data sets to determine these parameters. This presents a challenge to data owners who do not have a convenient data centre at their disposal: the size of data and computational cost in order to extract accurate models begins to look prohibitive. So we look to outsourced computation where computation can be ‘rented’ on demand to run analytics workloads.

One doubt remains. If we send our data off to the cloud, what guarantee do we receive that the processing has been done to our satisfaction? The provider has an economic incentive to cut corners: to perform the computation on only a sample of provided data, or to terminate an iterative parameter search before convergence has occurred, for example. Such short cuts yield plausible but suboptimal answers. So how could we be assured that the correct model has been found, without repeating the computation ourselves or paying independent providers to repeat the work, substantially driving up the costs?

II. RESULTS

Ideas of “interactive proofs” originally developed as a thought-experiment in computational complexity have led to methods that can check outsourced computations very effectively [1], [2], [3]. Applied here, they require the cloud to give a “proof” that can be checked easily by the data owner, shown schematically in Figure 1 [4], [5]. This lightning talk will give some examples of data analytics problems for which there are ultra-efficient proof protocols. The overhead for the cloud provider is minimal – often, the required information is a relatively low cost function of the input data or natural by-products of the target computation. These do not restrict the cloud to use any particular implementation or algorithm; just that they demonstrate that the output meets certain necessary properties. The key part of these protocols is that the information required is very easy for the original data owner to

check, based on appropriately defined fingerprints computed flexibly from the input. If the data owner’s checks pass, then they are assured that the computation has been performed by the cloud satisfactorily, with a very high degree of certainty. One can then think of these protocols as providing effective “checksums for computation”.

ACKNOWLEDGMENTS

This talk is based on a sequence of works, the most recent of which is [6].
