1   **Micro-structure and morphology characterization of nZVI treated**

2   **clay with Pb contamination**

3   **Abstract:**

4   The increasing use of nanoscale zero-valent iron (nZVI) for soil and groundwater

5   remediation is raising some concerns regarding the potential effect of the soil properties.

6   Numerous laboratory and field studies reveal that an excellent immobilized efficiency

7   of contaminants and enhancement of the contaminated soil by nZVI. Few researches

8   focused on the effect of the nZVI on the micro-structure and morphology of the soil.

9   The overall objective of this study is to explore the particle morphology and micro-

10   structure variation of nZVI treated soil. This study presents a series of microscales

11   experiments on nZVI treated samples, including field emission scanning electron

12   microscopy (FESEM), particle size analysis, mercury injection porosimetry (MIP),

13   optical microscopic analysis and particle shape tests. The dosages of nZVI were used

14   at 0%, 0.2%, 1%, 5% and 10% of the contaminated soil. The morphology tests suggest

15   that the addition of nZVI resulted in the presence of larger particle size, on-particle

16   chained structure, aggregation and network of flocculent structure. The aggregated and

17   bonded soil particles could be one of the mechanisms of the geotechnical characteristics

18   variation and soil enhancement via nZVI.

1. Introduction

Nanoscale zero-valent iron (nZVI), with its strong reducing property and high reactivity, have potential for use in remediation of a wide range of hazardous pollutants as indicated. It can react with organic contaminants and heavy metal ions, including Pb^{2+}, Ni^{2+}, As^{2+}, Co^{2+}, Cu^{2+}, CrO_4^{2-}, AsO_4^{3-}, polycyclic aromatic hydrocarbons (PAH) etc. in bench-scale and pilot-scale experiments (Mueller et al. 2012, Singh et al. 2012, Chekli et al. 2016, Tiberg et al. 2016, Wang et al. 2016, Gil-Díaz et al. 2017, Li et al. 2017, Moazeni et al. 2017, Jiang et al. 2018). The nZVI efficiency of aqueous, contaminated groundwater was proved in many literatures. For example, the lab synthesized nZVI - removal of lead ions in aqueous phase was verified the reduced efficiency of 99 % in less than 15 mins (Xi et al. 2010), 96% within 3 hours (Kim et al. 2013) and 96% of heavy metal ions (e.g. copper, arsenic, zinc and nickel) in 10 mins (Li et al. 2017). As mentioned in Liu et al. (2018), the nZVI shows an excellent on immobilization percentage of lead on only 0.2% of nZVI can reach up to 78.8% by testing the consolidated soil, and 95.6% achieved at 10% nZVI (soil wt.).   The adsorption, reduction and co-precipitation of ferrites were identified as the predominant process in immobilization (Noubactep 2008, Xi et al. 2010, Tu et al. 2012, Arancibia-Miranda et al. 2014, Wang et al. 2016).

Due to its efficient properties, nZVI has been used for the treatment of contaminated subsurface soil and groundwater. However, the effect of nZVI on the geotechnical properties are still not fully understood. Traditionally, in the applications, nZVI suspension was directly injected into the aquifer or permeable reactive barrier (PRB) to remove contaminants in the target area. However, during this process, nZVI particles are prone to agglomerate mutually or adsorbed onto soil grains, leading to a reduction of surface area (Noubactep 2008, Sarathy et al. 2008, Mueller et al. 2012, Chowdhury et al. 2015, Li et al. 2017). Luo et al. (2012) also found that the utilization of nano aluminium oxide enhanced the unconfined compressive strength of treated sewage sludge ash by the soil slurry preparation while the permeability increased. Ng and Coo

51 (2015) reported that the permeability of nano copper oxide treated clay significantly

52 decreased using the compacted samples while the liquid limit decreased. It is indicated

53 that the plasticity index reduced with the nanomaterials and liquid limit increased

54 (Ghasabkolaei et al. 2017, Zhou et al. 2018). It should be noted that the effect of

55 different nanomaterials on the soil plasticity need to be on a case by case basis.

56 Limited information is currently available on the shear strength of soil interacted with

57 chemicals and nanomaterials. It is concluded that the compaction characteristics and

58 compressive strength of the soil were improved by nano clay, nano copper, nano

59 alumina and nano silica (Bahmani et al. 2014, Iranpour and haddad 2016). As for the

60 nZVI treatment of the oil contaminated soil, the significant increases of unconfined

61 shear strength, friction angle and cohesion were observed using the compacted samples

62 (Nasehi et al. 2015). Zhou et al., (2018) and Chen et al., (2018) utilized the different

63 dosages of NZVI to exam the variation of the shear strength and compression behavior

64 of the lead contaminate clay sample which was prepared through a slurry consolidated

65 method. Upon NZVI treatment, a significant shear strength, including the vane shear

66 strength and the friction angle, increased was observed.

67 To understand how nanomaterials affect it is important, first, to understand how it

68 interacts with the clay-water system (Boardman, 2004). The aggregation of nZVI was

69 considered as a dominant physical effect in the solution (Phenrat et al. 2007). Several

70 potential mechanisms were proposed to explain the increase in shear strength with

71 NZVI is attributed to multi factors, including the immobilization/degradation of heavy

72 metal, changing in the DDL thickness, conglomeration and the aggregated properties

73 of nanomaterials (Ghasabkolaei et al. 2017, Liu et al. 2018, Zhou et al. 2018). The iron

74 oxides was considered as one of the important factors in the formation of pores and

75 aggregates (Regelink et al. 2015). Yet, there is no universally accepted way to

76 characterize the soil structure (Díaz-Zorita et al., 2002). Considering the variation of

77 the geotechnical properties nZVI or nanomaterials treated soil, limited literature update

78 its characterization mechanism how the nZVI reacted with the soil.

79   The overall objective of this study is to evaluate the nZVI on the characterization of

80   lead contaminated soil. This study presents a series of microstructural assessments,

81   including field emission scanning electron microscopy (FESEM), Laser diffraction

82   analysis, mercury injection porosimetry (MIP), optical microscopic analysis, and

83   particle shape tests at various levels of nZVI (i.e. 0.2%, 1%, 5% and 10%). The samples

84   in this study were prepared following the procedure described by Zhou et al. (2018).

85

86   **2. Materials and Methods**

87   *2.1 Materials*

88   The soil from a local site in Macau was used. The obtained soil was moist sieved

89   through 1 mm and used as matrix material to investigate the multi scale properties of

90   lead-contaminated soil and nZVI treated soil. The Atterberg limits are composed of

91   liquid limit (LL), plastic limit (PL) and plasticity index (PI) defined by the ASTM

92   standard test method - ASTM D4318. The dominant mineral of the natural soil is quartz

93   and its composition consist of Chlorite, illite, kaolinite, anhydrite and plagioclase. The

94   similar results was report in the previous research (Yan and Ma 2010). Moreover, a laser

95   diffraction analysis of the marine clay showed that the soil contained 20% clay, 70%

96   silt, and 10% sand fractions. The liquid limit, plastic limit and plasticity index of the

97   soil was found to be 62%, 32% and 29% respectively. The soil was defined as CL

98   according to the unified soil classification system (USCS).

99   The based soil (i.e. natural soil) was mixed with distilled water equal to the moisture

100   of 2LL. The contaminated reagent was utilized the lead nitrate (AR) obtained for

101   XiLong Chemical Co. Ltd and mechanically mixed with the natural soil slurry. Notably,

102   the contaminated concentration was 500 mg/kg lead ions (dry weight) and the produced

103   slurry was standing for 48 hours to achieve an equilibrium status. It is noticed that the

104   normal value of lead ions is less than 100 mg/kg(wt.) in a conventional contaminated

105   condition. The composition of the sludge from highly polluted rivers and mining

106   sediments may contain various heavy metal pollutants and high concentration (e.g. Pb-

107 44.1, Cr-173, Zn-154, Cu-49.7 mg/kg, etc.) (Zhang et al. 2009). However, the

108 superimposed concentration of multiple contaminants is likely to reach even more than

109 500 mg/kg (wt.).

110 The treatment was that four dosages (0.2%, 1%, 5% and 10%, by dry weight) of

111 nZVI were added into the contaminated soil slurry while mixed by the electric-agitator

112 for a better dispersion. Nano zero-valent irons (nZVI) as the treated reagent supplied

113 by XiangTian Corp. In order to prevent oxidation of nZVI, the nZVI powders were

114 sealed in a nitrogen-filled packaging. The characterizations of nZVI are as follows:

115 Median radius size of about 50 nm, Purity of 99.9 %, BET Specific surface area (SSA)

116 of 30 m^2/g, Bulk density of 0.48 g/cm^3 and Density of 7.9 g/cm^3. In mixing period, it

117 can be regarded as oxygenated and waterish condition, by which the nZVI can fully

118 react with the ions and clay particles. The time refer to the optimal reaction time (e.g.

119 5 mins) for the aqueous solution (Kaewbuddee et al. 2016). Considering the soil

120 complexity, it is essential to set the concentration of the treatment reagents matching

121 the contaminants. It is reported that the nZVI performed a higher removal efficiency

122 when the molar ratio of nZVI/lead and nZVI/nitrate is 10 and 4 respectively in the

123 solution(Su et al. 2014, Moazeni et al. 2017). The dosages of nZVI was used as 0.2%,

124 1%, 5% and 10% (dry density) corresponding to the molar content of nZVI is 15, 75,

125 370 and 740. Due to the complex minerals in the soil, the removal efficiency was not

126 comparable to that in solution. It may potentially lead to overestimates of the extent of

127 degradation attributable to nZVI. Thus, the ratio of lead vs nZVI represents the

128 proportional condition to excess condition as mentioned in (Zhou et al. 2018).

129 The produced slurries were consolidated in a double draining consolidation tank at

130 an effective vertical pressure of about 200 kPa. After that, the soils were extracted for

131 the basic property tests, FESEM, particle size tests, MIP, optical microscopic analysis,

132 and particle shape tests.

133

2.2 Experimental Methods

135   Slurry consolidated method was used for an efficient reaction among nZVI, water

136   and soil. Furthermore, the consolidated process was identified as anaerobic condition

137   and helpful for simulating the natural process. When the nanoparticles were uniformly

138   dispersed in the semi-dried soil, nanoparticles can fill the void among particles instead

139   of aggregating rapidly. The self-organized structure (e.g. aggregates and gelled

140   networks) of nanomaterial treated soil in the waterish environment has the effective

141   impact on the geotechnical properties (Phenrat et al. 2007).

142   The microstructures and morphologies of the clay mixtures were analyzed using field

143   emission scanning electron microscope (FESEM, ZEISS Gemini300, Germany). Prior

144   to use, the soil particles were dehydrated by the freeze-vacuum method to remove free

145   water completely. The samples were transferred to the sputter coaters for conductive

146   coating with platinum (Pt) and put it into the scanning electron microscope for

147   examination.

148   The particle size distribution (PSD) was carried out by a laser diffraction Mastersizer

149   (Malvern 3000, UK), following ASTM D2487 (2006). Before tests, the samples were

150   stirred and homogenized by ultrasonic method at least 5 mins.

151   The pore size distribution of the consolidated samples was measured by using an

152   Autopore IV 9500 mercury intrusion porosimeter (Micromeritics Corp. USA) with 414

153   MPa entrance pressure. Considering the negative effect of oven drying method on the

154   microstructures, the freeze-drying method was selected for dehydration (Gallé

155   2001).The nano-scale pore size distribution is a strong evidence for the micro structure

156   change of undisturbed sample affected by nZVI. The MIP is regarded as an excellent

157   tools to explore the soil pore size distribution with the minimum damage to the pore

158   structure (LAWRENCE 1978, Arvaniti et al. 2015, Li et al. 2015).

159   The microscopy was conducted by the Nikon microscope (Nikon E200, Japan)

160   equipped with the Nikon DS-L3 image capture system. For the image clearness,

161   microscope images were digitalized. Briefly, a few grammas of samples after pre-

162 consolidation were selected and diluted with distilled water for 200% moisture content

163 in order to obtain a homogenized soil slurry. The slurries were sealed and maintained

164 at 25°C for 24 hours. Then, the soil slurry was fivefold diluted using ultrapure distilled

165 water and shaken vigorously for 30 s using vortex shaker 3 (IKA, Germany). Each

166 sample were replicated twice at 100× to 1000× magnification. This method would be a

167 few approach for evaluate the micrometer-sized structure under the waterish condition

168 (Phenrat et al. 2007). The sample requires no conductive coating on the specimen under

169 100X to 1000X magnification (i.e. around 50 -250 µm). This makes it possible to

170 examine the liquid samples and to preserve their natural characteristics and water-

171 steady aggregates for further observation, which is an obvious advantage of this

172 compared to the traditional morphological techniques (e.g. SEM) (Gillott 1970).

173 The particle shape analysis was performed by the 500 Nano Zephyr LDA (Laser

174 Diffraction Alternative) analyzer (OCCHIO, Belgium). This system consists of a

175 vacuum dispersion device and high-resolution camera with a collimated telecentric lens

176 which can be used for imaging the particles. In this study, the soil particles were

177 smashed and dried by freeze-vacuum method. Size and shape analyses used in this

178 paper have been performed with Occhio's Callisto software which implements best

179 practices of image analysis. Digital image analysis of individual particles has long been

180 recognized as a powerful tool to measure both size and shape parameters and superior

181 to laser diffraction for the irregularly particles, such soil particles (Leroy et al. 2011,

182 Arvaniti et al. 2015).

183 The specimens were identified using designated notations: NS for natural soil (Virgin

184 soil), PS for Pb^{2+} contaminated soil, and PSN1 for the soil treated with 1%

185 concentration nZVI. The experimental procedure is summarized in Table 1.

Table 1 Experimental design

Equipment	Objective	Scale (μm)	Specimens
Field emission scanning electron microscope (FESEM)	Morphology	1-3	NS, PS, PSN0.2, PSN5, PSN10, NSN5
laser diffraction Mastersizer	Particle size distribution	0.1-1000	NS, PS, PSN0.2, PSN1, PSN5, PSN10
Optical microscope	Micro structure (Waterish)	50-250	NS, PS, PSN1, PSN5, PSN10, NSN5
Mercury intrusion porosimeter (MIP)	Pore size distribution	0.01-100	NS, PS, PSN1, PSN5, PSN10
Nano Zephyr LDA analyzer	Particle shape analysis	25	NS, PS, PSN10

4. Results and discussion

4.1 FESEM analysis

In order to study the morphological change of particles with great enlargement factor (i.e. up to 1 μm), the particle images from FESEM were shown in Fig. 1. It should be noted that the black background/ shadow is incomplete coating or out of the focal plane because of the spatial structure of the complex shape, rather than a blank area. It provided conclusive proof on the presence of smaller particles and more particle-particle space. The SEM image of natural clay exhibits the superimposition of the dense structure. Examining the image sequence in order of increasing magnification, the fragmentation and crossed structure of contaminated soil may also serve as caused by the lead ions.

After mixing nZVI additive, the microstructure was then conducted to demonstrate the effects of the reaction concentration of nZVI. More cross-linked and conjoint structures were observed. Especially, clastic soil particles become gradually lessened. Meanwhile, it is evident that cross-linked and schistose structures is in the majority, as shown in (f) for NSN5. FESEM images of the treated soil sample show that schistose and laminar texture-like structures formed obviously depending on the nZVI reaction，especially in c) PSN0.2, e) PSN10 and (f) NSN5. The schistose structures of the larger dosage become less evident and degree of reticulation appears to increase.

This may be attributed to the formation of elemental lead and ferrite via redox reaction and the aggregation of nZVI (Fig. 6), which changes the morphology of particle surface and connections. The morphological results were consistent with the research reported by Xi et al. (2010) and Mar Gil-Díaz et al., (2014). The variation of morphology should be ascribed to the flocculation of nZVI-Pb-soil and the formation of ferrite/ oxides/hydroxides with nZVI additive. The results suggest that the use of nZVI in the soil can produce more structural connection, which could be considered as the main reason of the engineering properties. This is consistent with the observation of the particle shape, pore size and soil micro-structure. All these results are supported

216 by FESEM observations and highlight the fact that the geotechnical properties changes

217 are due to a reorganization of the particles leading to fabric changes (Souli et al. 2008).

218   It cannot be denied that the change of the particle morphology could have an impact

219 on the geotechnical properties. However, Young et al. (2001) questioned that the

220 aggregates through the morphological technologies was the result of how we choose to

221 observe them. Thus, the pore size distribution was considered as the key evidence to

222 support the assumption of the micro-structures change.
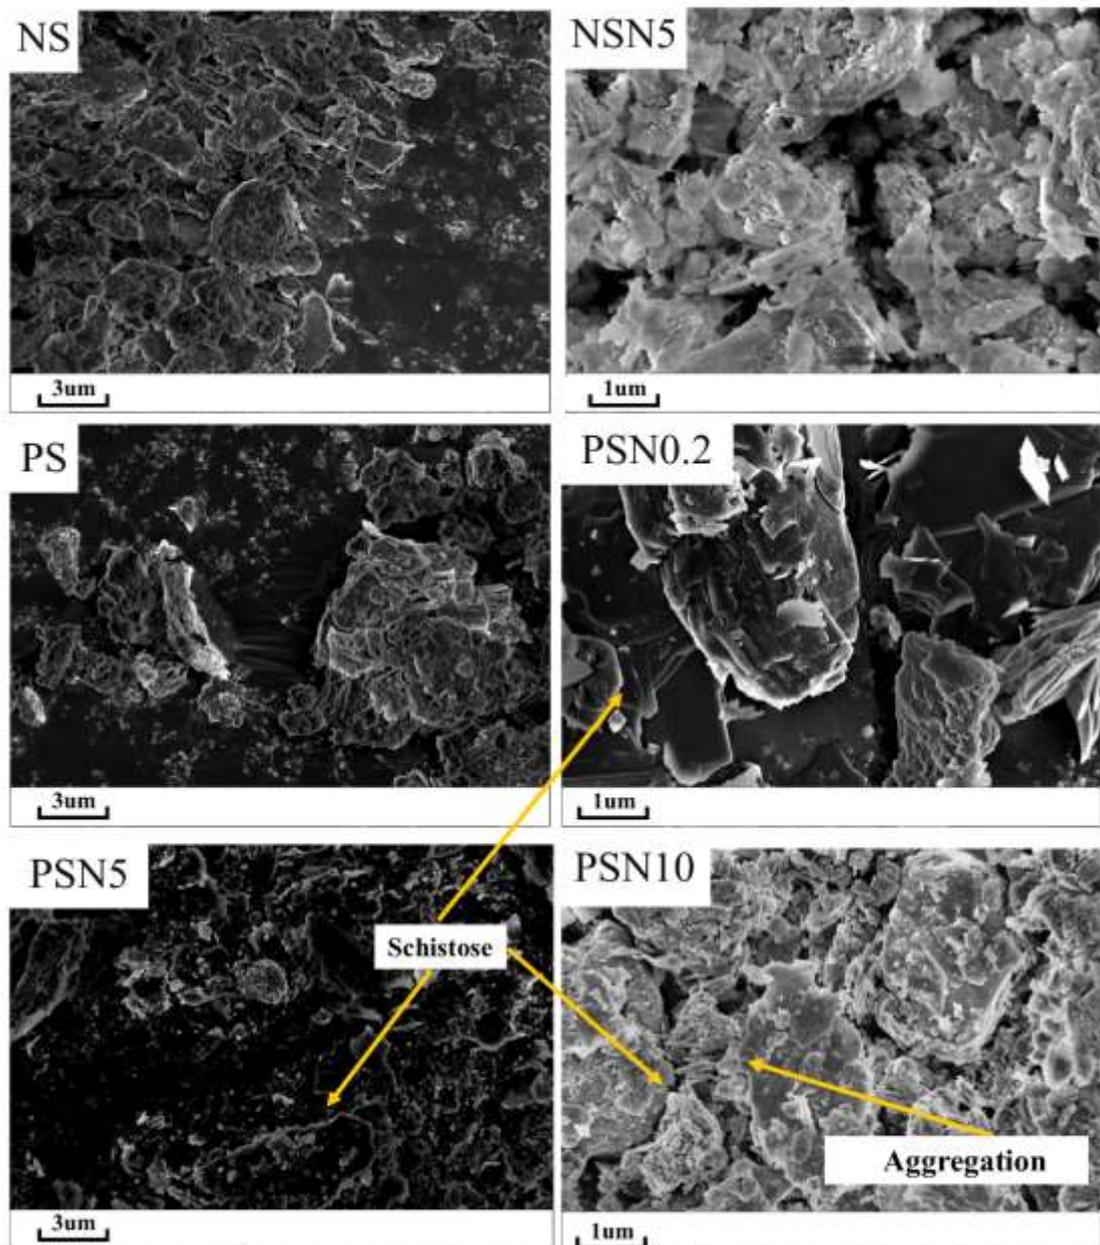

223

224 **Fig. 1** FESEM results of nZVI treated soil at different dosages: (a) Natural soil (NS);
225 (b) NSN5; (c) PS; (d) PSN0.2, (e) PSN5 and (f) for PSN10

227 *4.2 Particle size distribution*

228 Fig. 2 shows the particle size distribution of each sample and pure nZVI. The particle

229 size distribution shows the scale impact from 0.1 to 2000 µm. Four typical curves are

230 shown for a clear view. The particle size distribution of contaminated soil tends to more

231 fine particles than that of natural soil. This could be due to the rearrangement of the

232 double layer or the reacted precipitation (Helios Rybicka et al. 1995, Schmitz et al. 2004,

233 Du et al. 2015). On the other hand, with the increasing concentration of nZVI, the

234 particle size distribution curves shifted to the right, which means that larger size

235 particles appeared. The addition of nZVI from 1% to 10% results in an increment 15.6%

236 of sand percentage. Meanwhile, the clay-size percentage of specific soil decrease from

237 26.8% to 19.6%. Once the nZVI was added into the water, some large-scale particles or

238 structures (with $D_{50} = 22$ um) appeared due to the nature of aggregation and magnetism.

239
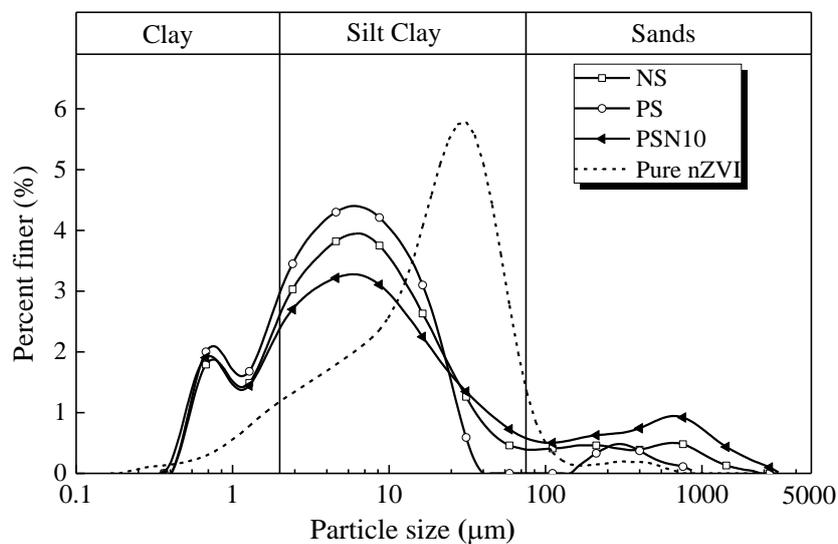

240

241　　　　**Fig. 2.** Particle size distribution of treated sample and nZVI in the solution

242

243　　　The results of the specific diameter are shown in Fig. 3. The D_{10}, D_{50} and D_{90}

244 proceeded in a gradual manner with the inclusion of nZVI dosage. It is noted that the

245 D_{10} and D_{50} slightly decrease with the presence of nZVI less than 1%. The D_{10} was

246 around 1 um on the whole and increase efficiently with the 5% and 10 % nZVI (24.2%

247 increment). Furthermore, the trend of D_{50} was consistent with that of D_{10}. The D_{50} of

248 10% nZVI has a 19.5% growth. As considering the D_{90}, the value has a little change

249 when the dosage is less than 5%. With the introduction of 10% nZVI, the D_{90} increases

250 significantly from 25 to 321 µm. However, it has a larger relative standard deviation

251 which means the non-uniformity of the large particles. Possibly, it could result from the

252 high reactivity of nZVI and hence the excess nZVI lead to drastic formation of the

253 cross-linked aggregations and bounded structure. Previous studies reported that the

254 nanoparticles tend to form much larger (e.g., microscale) aggregates in the absence of

255 surface-active dispersants. The changes in clay- and sand-sized particle percentages in

256 the stabilized soils are dominantly attributed to both short-term flocculation formation

257 and long-term oxidation reactions (Nalbantoglu and Tuncer 2001, Tran et al. 2014, Xia

258 et al. 2017). Both mechanisms of nZVI in the soil could result in a higher percentage

259 of particle or bounded aggregations (Phenrat et al. 2007, Li et al. 2008, Moazeni et al.

260 2017). He et al. (2008) indicated that different particle sizes show different tendency to

261 aggregate.
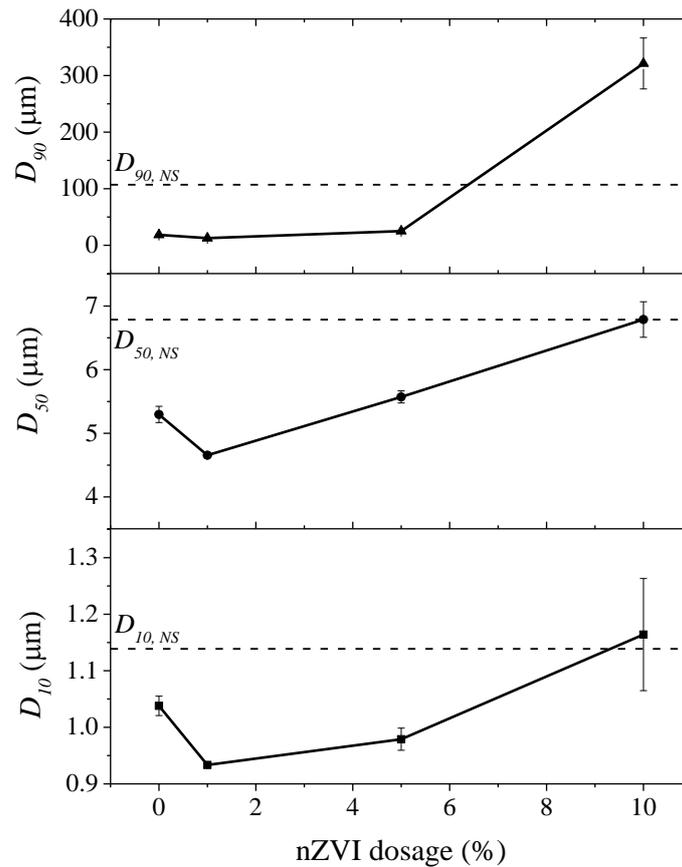

Fig. 3. Particle size diameter results from the PSD tests Error bars represent RSD (n = 5, Relative Standard Deviation)

4.3 Pore size distribution

In the following, the results are analyzed with respect to the evolution of the pore size distribution. The samples were treated with different dosages and consolidated, by which the final void ratio could be various due to the change of geotechnical properties. Hence, this section focuses on the change of pore size and explore the variation of soil structure. In all the soil cases, the pore size distributions show an intrusion at a pressure corresponding to a threshold diameter close to 0.003 μm and up to 10 μm.
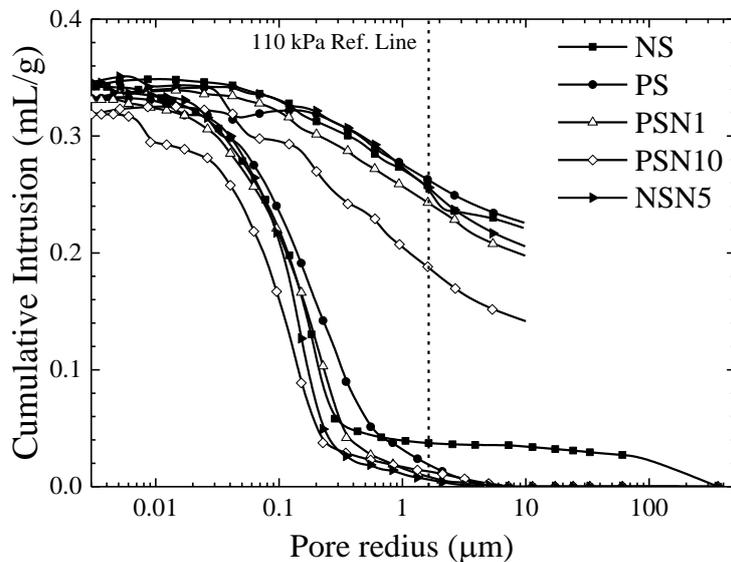

The Fig. 4 presents the mercury intrusion and extrusion curves for treated and untreated soil. Five typical curves are shown in this figure for a visible and distinguishable view. With such a porous structure, mercury cannot intrude into larger pores until the applied pressure is sufficient to force mercury to go through smaller

277   throats. As a result, the volume of these larger pores is counted as the volume of smaller

278   throats. This is referred to as the "accessibility effect" (Diamond 2000) The larger pores

279   that are accessible to mercury through smaller throats are called ink-bottle pores. And,

280   the smaller throats are called throat pores. As a result, the MIP measurement provides

281   an underestimation of the volume of the large pore and an overestimation of the volume

282   of the small pore. According to Ramakrishanan et al. (1998) self-consistent pore-

283   body/pore-throat ratios can be obtained from the measured hysteresis between the

284   intrusion and extrusion curves (Anovitz and Cole 2015). Therefore, for all samples, a

285   large hysteresis is presented between mercury intrusion and extrusion curves. This

286   phenomenon could be explained by poor connectivity of pore network

287   Due to the initial vacuum procedure, the extrusion efficiency was calculated by the

288   cumulative extrusion /cumulative intrusion value at around 110 kPa. It represents the

289   ratio between the volume of the connective pore and that of total pore. The mercury

290   extrusion curves of the nZVI treated samples present more significant differences with

291   that of untreated sample. The mercury extrusion efficiency increases with nZVI dosage

292   to 22.14% (PS), 27.25% (PSN1), 28.79% (PSN5) and 42.66% (PSN10) respectively. It

293   indicates that most of the intruded mercury is still trapped in the soil due to the ink

294   bottle and throat effect, which shows a poor connectivity of the natural soil. However,

295   it can be noted that the proportion of the connective pores increases with the nZVI and

296   hence that the change of the inter-aggregate connection can be deduced.

297   It indicated that the slightly increasing segment of the intrusion (i.e. late stage of the

298   curve) could be one of the effective methods to distinguish the intra-aggregate pores

299   (Sakhaee-Pour and Bryant 2014). The turning point was calculated as the maximum

300   tangent slope. The late stages proportion of NS and PS are less than 1%. However, that

301   of PSN1, PSN5, PSN10 and NSN5 are around 9.6%, 10.9%, 14.2% and 10.2%,

302   respectively. Thus, it was acceptable that the inclusion of the nZVI has a great influence

303   on the intra-aggregate pores. The intra-aggregate pores were highly correlated with the

304   addition of the nanomaterials.

305   From the further analysis, it is noted that the pore volume and the pore size reduce

306   with the introduction of nZVI in both. The increase of the initial threshold pore entrance

307   diameter was observed as well, which was used as one of the evaluation criteria of the

308   pores (Burton et al. 2015). It has been well documented that the cross-linked structure

309   of the nZVI dispersion could create an impermeable barrier and thus plug the pore

310   spaces and thereby lead to the decrease of pore size (Phenrat et al. 2007, He et al. 2010,

311   Chowdhury et al. 2015, Li et al. 2016). The decrease of pore volume and pore diameter

312   distribution is considered to generate a more compact structure in the soil skeleton, and

313   hence has a gain in enhancement. The inter-aggregate and pores have remarkable

314   effects on the strength properties of soils, as a result, the soil samples stabilized with

315   higher content of nZVI have superior mechanical performances than those stabilized

316   with lower content of nZVI (Horpibulsuk et al. 2009, Jiang et al. 2014, 2016).

317

318

319   Fig. 4. Mercury intrusion and extrusion curves of the samples

320

321   Fig. 5 present the MIP pore size distribution curves for the natural soil and treated

322   soil. It presents that the main peak intensity ranges from 0.1-0.4 μm with a dominant

323   peak. The curve shape shows a major peak and a sub-peak intrusion in some cases. That

324   means the Soil-Pore structures dominated the soil skeleton with the addition. The

325 variation of pore size distribution could be summarized as the dual-structure (i.e.

326 interaggregate pores and intra-aggregate pores) (Li and Zhang 2009).

327   As the comparison to the NS and PS results, it indicates that the addition of lead

328 contaminants may lead to generate a larger pore (0.3-0.8 µm) and the peak was not

329 obvious which could be attributed to the thickness of the diffused double layer. Lead

330 ions in soil may break the charge balance between the soil particles due to the

331 exchangeable valent cations and result in the increase in the repulsive force of the

332 contaminated soil particles. The presence of cations can affect the particle stability of

333 nZVI particles and result in more large pores among the aggregates (He and Zhao 2007).

334   Compared with the natural soil, contaminated soil, PSN1, PSN5, PSN10 and NSN5,

335 the curves shift to the left, which means the increase in the smaller pores. With the

336 presence of 1% nZVI, the proportion of the pores with 0.3-0.7 µm decreases. The curves

337 of PSN5 and PSN10 have the similar trend with that of PSN1, such as 0.05-0.25 µm for

338 PSN5 and 0.12-0.5 µm for PSN10. As expected, the pore diameter decreases with the

339 nZVI addition from 1% to 10%, showing a porosity refinement due to the nano pore of

340 nZVI, nano-scale aggregation/precipitate. The nZVI aggregation of clay particles

341 tended to change the portion of both interaggregate pores and intra-aggregate pores.

342 The aggregated structure of nZVI dispersion could create a porous structure and thus

343 plug the pore spaces. This is because the nanomaterials (i.e. nZVI) or aggregates acted

344 as the bonding connections or filler in the void or the agglomeration (Chandni Dipak

345 and Srirama 2015, Ghasabkolaei et al. 2017). Ng and Coo (2015) indicates that the

346 largest pore size reduced by 20% when clay was mixed with 4% nano copper oxide.

347 The stiff aggregates form a strong connection to carry the compression force, which

348 could be the reasons for the nZVI enhancement (Taha and Taha 2012, Zhou et al. 2018).

349 Iron oxides have the ability to form strong bindings with clay, silt and sand particles,

350 meaning that iron oxides can provide sorption sites for organic substances on the

351 surfaces of these otherwise low to moderately reactive particles (Sei et al. 2002). The

352 iron oxides could enhance the formation of small-scale aggregates and soil pores (Lu

353 et al. 2014, Regelink et al. 2015). The Soil-nZVI structure (i.e. interaggregate pores)

354 could be one of the main reasons for the reduction of the large pores.

355   Due to the nano-scale materials, the pore size can be predicted as the increasing

356 proportion of micrometer-size or nanometer-size. Especially, a sub-peak intrusion, less

357 than 0.01 μm scale, is observed for the PSN10 and NSN5. It can be assumed that the

358 excess nZVI may result in the formation of the unreacted nZVI aggregation because of

359 the pores of the aggregates. Due to the ink bottle effect and throat effect, the volume of

360 the pores (less than 10 nm) could be overestimated. However, this issue is out of the

361 scope of this study. Thus, this tendency was acceptable. The intra-aggregate pores are

362 regarded as the nZVI-Pore structures. It confirmed that the extreme excess nZVI could

363 be not easily dispersed and generate the nZVI aggregates.

364
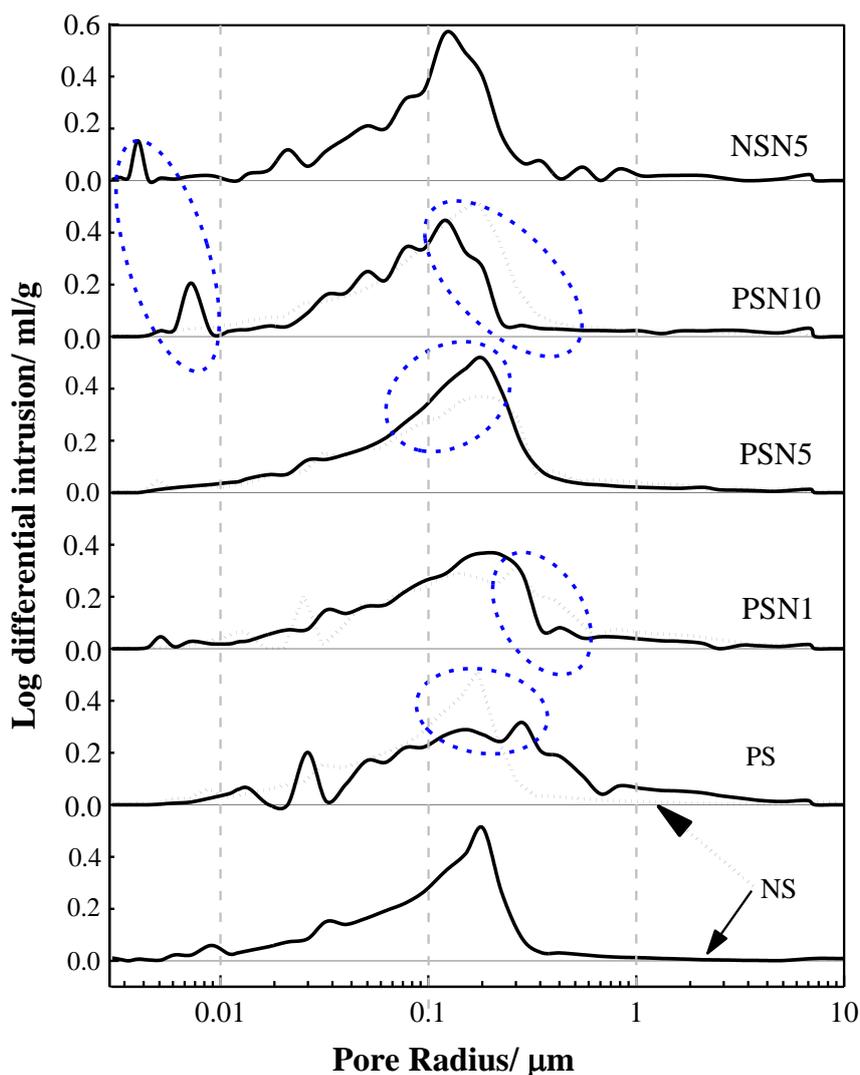

365   Fig. 5. Variations of differential intrusion with respect to pore radius.

366

367   *4.4 Optical microscopic analysis*

368   For clarifying the aggregation of nZVI in the waterish condition, the optical

369   microscopic analysis was conducted. This is one of the qualitative methods for studying

370   the arrangements of micro-structures in the soil (She et al. 2018). Although the SEM

371   technology has been a common method for the morphological analysis. However, some

372   of the samples were sensitive to the air or dried condition and exhibited different

373   structures, such as the soil. The water-steady structures are vital to the soil skeleton.

374   Fig. 6 notes the micrographs of pure nZVI in the distilled water under 1000X

375   magnification. After shaking vigorously, the existing structure could be regarded as a

376   strong bond among the soil particles. The formation of large aggregates and larger

377   chain-like fractal aggregates (around 50 um) was observed in the nZVI suspension

378   with/without shaking. The size of the observed aggregation is consistent with the

379   particle size distribution of pure nZVI in the water.

380   Although the size of the aggregates (micron-sized) is significantly larger than the

381   origin scale of nZVI (Nanometer-sized), previous studies reported that the nZVI tend

382   to form much larger aggregates under nanoscale magnifications in the dispersants (Li

383   et al. 2008). Some of the nZVI aggregates in the water are easy to be disturbed by

384   mechanical disturbance because the aggregation forces are the van der Waals and

385   magnetic forces (Phenrat et al. 2007, Kim et al. 2013). The observation of the loosely-

386   boned cluster still dominate the chain-like and network structure (He et al. 2010, Dorjee

387   et al. 2014, Chowdhury et al. 2015, Li et al. 2016). Chekli et al. (2016) shows similar

388   characterization evidences of nZVI. This observation could be one of the fundamental

389   evidences for the nZVI-soil aggregations.

390
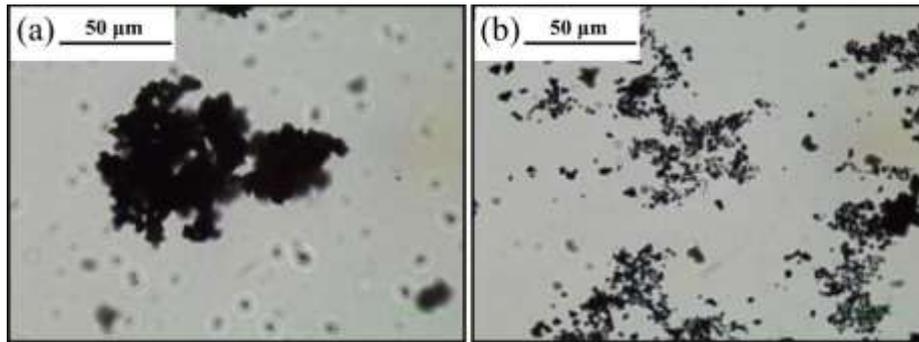

391

392 **Fig. 6**. Micrographs of pure nZVI under 1000X magnifications; (a) the origin nZVI in

393 the water, (b) the nZVI in the water after shaken vigorously for 180 s

394

395 Fig. 7 shows the digitalized micrographs of soil mixture at 100X magnification.

396 Aiming to obtain the convictive results and nZVI effects, the referral sample (i.e. NSN5)

397 was added in this series of microscopic tests. The black area was the soil particles and

398 the white area was the water. The suspensions of the samples in the water shows the

399 fabric structures. The images of NS show a homogeneous state of soil particles and few

400 aggregates. The micrographs of PS show a few flocculent aggregations in the horizon

401 and the particles are dispersive. With the nZVI treatment, the flocculation of the treated

402 samples become clearer, and large particles and more chain-like aggregates like the

403 nZVI structure were observed, by which it would be helpful to enhance the connection

404 between the particles. As the increase of the nZVI dosage, the aggregates (i.e. Black

405 area) become more distinguishable and the particle size increases. Compared to the NS

406 and NSN5, the inclusion of 5% nZVI has an efficient flocculation on the soil dispersion

407 and thereby more aggregates and connections are detected. This observation could be a

408 potential mechanism of the micro-structure properties of the wetting soil in the presence

409 of nZVI.

410
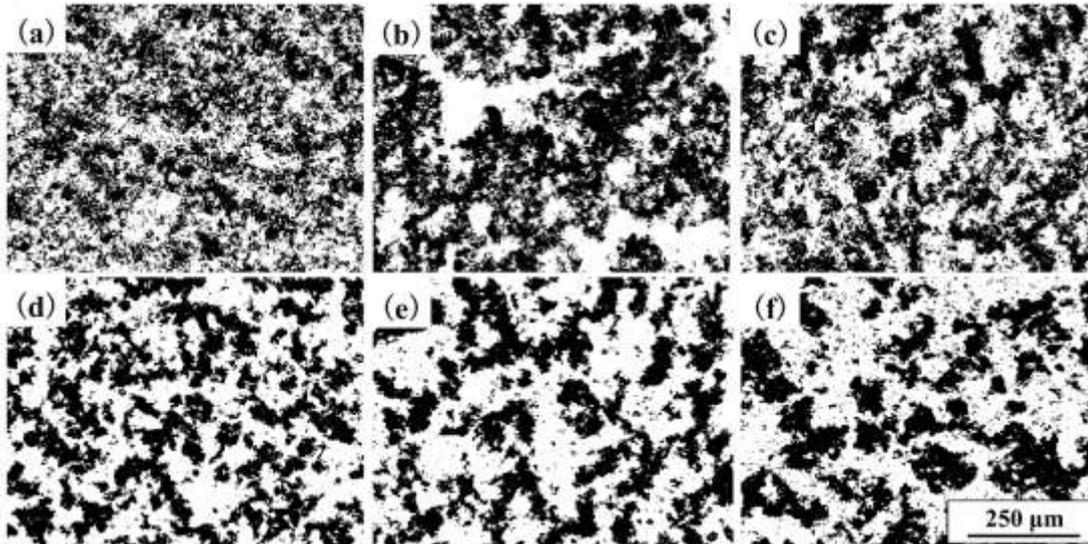

Fig. 7. Digitalized micrographs of the reacted specimens at 100X magnification: (a) NS, (b) PS, (c) PSN1, (d) PSN5, (e) PSN10 and (f) for NSN5

Fig. 8 shows the original state of NS, PSN10 and NSN5 under optical microscope with 1000X magnification. The scattered fraction of the soil particles was in the majority. As for the nZVI treated sample, the aggregations and larger particles can be monitored, which exhibited the cross-linked and chained structure compared to that of the NS. The morphology of the PSN10 particles exhibits the fractal and chain-like aggregates. This could be a solid evidence for the nZVI effect on the soil structure under waterish condition.
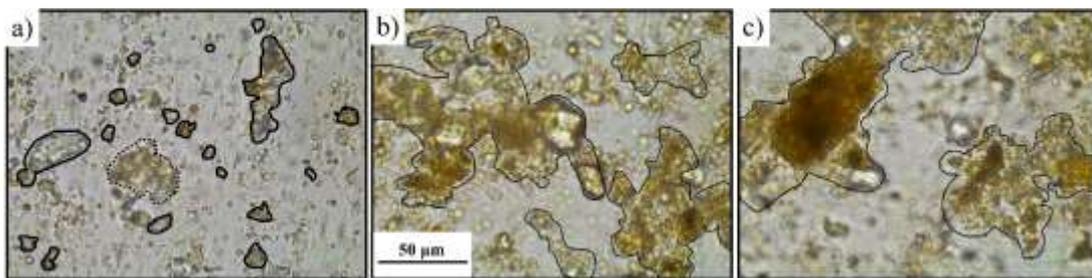

Fig. 8. Micrographs of reaction specimens 1000X magnification: (a) NS, (b) PSN10, (c) NSN5

These results show a consistent tendency, in which a clear microstructural change is detected at microscopic scale with the nZVI addition. As expected, the formation of larger chain- like aggregates from the individual micrometer-sized aggregates was observed in the Fig. 7 and Fig. 8. It is reasonable that nZVI treated sample exhibit a

430 higher percentage of larger-sized aggregates, which suggests that the more nZVI dosage

431 results in the acceleration of aggregates. It is an available route to estimate the

432 geotechnical properties on aqueous condition through the microscope. As for the

433 quantitative evaluation of soil microstructure. The structure of consolidated sample is

434 not only affected by microstructural changes, but the compaction. It would explain the

435 aggregation effect of nZVI and the increase of particle size in the PSD results. As for

436 the chain-like aggregation formation, that may influence the soil skeleton structure and

437 the engineering properties of nZVI treated soil.

438

439 *4.5 Particle shape analysis*

440   In addition to exploring the structural variations, the change of particle shape would

441 influence the engineering properties in a sub micro scale (i.e. dozens of microns, 25µm).

442 Hence, the particle shape photograph was conducted for exploring the effect of nZVI.

443 Considering the soil particles shape analysis, some typical optical pictures were

444 selected randomly from hundreds of particle shape images within reasonable scale. Due

445 to the incompleteness by the vacuum dispersion and the strong bound structure, two or

446 several soil particles cemented to each other may be observed as one particle sometimes.

447 However, for the particle size measurement technique, the obtained results are different

448 from the waterish condition (i.e. particle size analysis) and the dry condition. Here, this

449 section is focused on the change of the particle shape rather than the particle size

450 comparison.

451   The digitalized images of the particle shape selected from the similar particle size are

452 shown in Fig. 9. The results show chained structures on the surface of aggregation or

453 particle as the main variation with nZVI addition. It has demonstrated a consistent trend

454 with the observed structure of nZVI treated samples under the microscope. It can be

455 identified that some of particles could be bonded and the size close to about 50

456 micrometers because the incomplete dispersion, which is better to exhibit the cohesive

457 combination. Furthermore, it should be noted that the vacuum dispersion could break

458 the loose connection (e.g. the "tentacle" of the particles) before the tests. A possible

459 reason for this phenomenon is that the interacted production and precipitation of the

460 nZVI on the particle surface and the magnetic nature of nZVI could accelerate the

461 aggregation effect. It can be assumed that the chained structure on the particle surface

462 had linked each other in the undisturbed condition, by which the aggregate interlock

463 capacity (Micro effect) will become larger and result in the increase of strength (Macro

464 effect). In this case, the connectivity pore (MIP observed) could appear among the

465 aggregates with the chained structure.

466

467

468   **Fig. 9.** Digitalized particle shape images of the NS, PS and PSN10.

469

470 The main results of particle shape parameters are plotted in the Fig. 10. The global

471 surface concavity index (GSCI) was defined by the overall concavity of the projected

472 area of the particle. The roughness was the ratio of smooth reference to the particle

473 projection area. The smooth reference is defined by the inscribed circles tangent to each

474 point of the particle projection outline with a radius whose roughness value is the

475 percentage greater than the maximum inscribed circle. The volume-equivalent diameter

476 (D_v) was that the diameter of a sphere having the same volume as the particle (Wadell

477 1932).

478 From the images and parameter analysis, the variation of the particle shape can easily

479 be observed. For the nZVI addition for the treatment, the volume-equivalent diameter,

480 global surface concavity and roughness increase significantly. Meanwhile, the friction

481 angles increase, and the increment rate of the strength was similar to that of the

482 parameters. As expected, this change may be one of the mechanisms of the increase of

483 friction and soil resistance. Some literature stated that the increase of the particle

484 roughness and cementations could lead to an increase of the friction angle using a sand

485 sample (Cho et al. 2006, Rousé et al. 2008, Hassanlourad et al. 2011, Stark et al. 2014).

486 This could be another solid evidence for the nZVI effect on the soil structure and have

487 an impact on the mechanical characteristics.
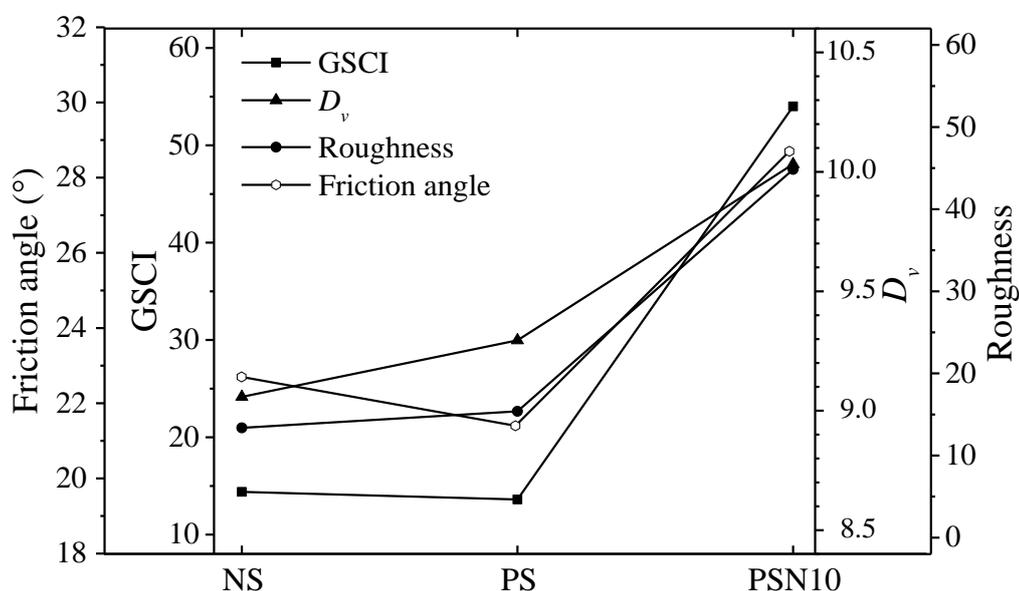

488
489
490 **Fig. 10.** Main shape parameters of the particle shape and friction angle

491

492 **5. Summary and conclusions**

493 In this study, an investigation of the nZVI effect on the microstructure was examined.

494 The FESEM analysis shows that the nZVI treated samples presented more schistose

495 and aggregated structures. The nZVI addition results in an increase of particle size and

496 finer pore size, which represented the formation of the dense structure with the

497 nanomaterials. The optical microscopic analysis and particle shape experiments

498   demonstrates that the nZVI addition induced aggregations and chain-like structures that

499   could be bonded to a network structure in the consolidated sample. Meanwhile, the

500   nZVI influence the soil skeletal structure and the engineering properties of nZVI treated

501   soil. The particle shape analysis confirmed the change of the particles morphology.

502   Some possible explanations for the soil enhancement are deduced including: the larger

503   particle size, formation of chained aggregation, cross-linked on-surface structures,

504   larger particle roughness. The findings would be beneficial for understanding the

505   mechanism and engineering behaviors of nZVI treated soil. The mechanism needs to

506   be investigated in depth.
