Abstract

Photoperiod sensors allow physiological adaptation to the changing seasons. The external coincidence hypothesis postulates that a light-responsive regulator is modulated by a circadian rhythm. Sufficient data are available to test this quantitatively in plants, though not yet in animals. In Arabidopsis, the clock-regulated genes *CONSTANS (CO)* and *FLAVIN, KELCH, F-BOX (FKF1)* and their light-sensitive proteins are thought to form an external coincidence sensor. We use 40 time-series of molecular data to model the integration of light and timing information by *CO*, its target gene *FLOWERING LOCUS T (FT)*, and the circadian clock. Among other predictions, the models show that FKF1 activates *FT*. We demonstrate experimentally that this effect is independent of the known activation of *CO* by FKF1, thus we locate a major, novel controller of photoperiodism. External coincidence is part of a complex photoperiod sensor: modelling makes this complexity explicit and may thus contribute to crop improvement.

Introduction

Many eukaryotes measure changes in day length (photoperiod), in order to synchronise their life strategies with seasonal rhythms. The photoperiod sensor in vertebrates is thought to be located in the pars tuberalis of the pituitary gland, though its molecular mechanisms are unclear (reviewed in Hazlerigg and Loudon, 2008). Daylength perception in plants occurs in leaves, giving rise to a long-range signal. In Arabidopsis thaliana, a signal induced by long photoperiods controls the transition to flowering at the apical meristem. Other plant species initiate over-wintering adaptations, such as bud dormancy and tuber formation, in response to short photoperiods (Thomas and Vince-Prue, 1997). Photoperiod measurement depends upon an interaction between photoreceptors and the 24-hour circadian clock. In Arabidopsis, the clock-controlled transcription of the B-box factor CONSTANS (CO) leads to a CO mRNA profile that peaks late in the day. High CO mRNA levels coincide largely with the light interval under long-day conditions (such as 16L:8D, a cycle of 16 hours of light and 8 hours of darkness), but are restricted to the dark phase under short days (8L:16D) (Suarez-Lopez et al., 2001). The major target of CO, the gene FLOWERING LOCUS T (FT), is expressed after the CO peak, but only when CO expression coincides with light (Yanovsky and Kay, 2002). This led to the hypothesis that CO may activate FT transcription in a light-dependent manner (reviewed in Carré et al., 2006; Imaizumi and Kay, 2006). More recently, the CO protein was shown to be unstable in darkness, partly due to interaction with COP1 (Jang et al., 2008), but to accumulate under constant white or blue light (Valverde et al., 2004). Thus, stabilization of the CO protein in the light may account for the lightdependency of CO effects on FT. This regulation occurs in the phloem companion cells (An et al., 2004), allowing rapid transport of the FT protein product to the apical

meristem (reviewed in Kobayashi and Weigel, 2007; Turck et al., 2008). There, interaction with the meristem-specific transcription factor FD activates the homeotic genes that lead to floral development (reviewed in Kobayashi and Weigel, 2007; Turck et al., 2008).

This molecular mechanism is consistent with the long-standing hypothesis that daylength perception is mediated through coincidence of an endogenous rhythm with an external light signal (Bünning, 1936). Expressing this hypothesis in equations shows that the rhythmic component could be a generic, clock-controlled gene with expression levels that rise towards the end of a long photoperiod (Oosterom et al., 2004). This contrasts with the "internal coincidence model" that may apply in vertebrates (Hazlerigg and Loudon, 2008) in which photoperiod acts to bring two circadian rhythms into a particular phase relationship (Pittendrigh, 1960). Recent evidence suggests that the mechanism of daylength perception in plants may be more complex than either conceptual model. For example, expression of the CO mRNA at the end of long-day photoperiods is mediated in part through the action of a rhythmically expressed, light-activated F-box-Kelch protein known as FKF1 (reviewed in Imaizumi and Kay, 2006). High FKF1 protein levels coincide with the light interval at the end of a long day, when FKF1-mediated degradation of transcriptional repressors in the CYCLING DOF FACTOR family promote transcription of CO (Fornara et al., 2009; Imaizumi et al., 2005; Sawa et al., 2007). Under short day conditions, FKF1 is expressed in the dark and appears inactive. This external coincidence between light and the FKF1 expression rhythm affects the CO expression rhythm: the level of CO protein may therefore integrate the output of two external coincidence sensors.

Here, we model the photoperiod sensor of Arabidopsis in detail, based upon molecular timeseries data. We aim to test whether the expression patterns of the known flowering-time genes are quantitatively consistent with their proposed regulatory functions, and whether these functions are sufficient to explain the observed behaviour of the plant. Analysis of the models confirms our understanding of flowering time regulation in some areas. Specific failures of the models in other areas predict new regulatory interactions or components that can be tested by molecular experimentation.

Results

Model construction and data selection

The regulatory network was represented in ordinary differential equations, where the form of the equations reflected the known molecular interactions. Model construction proceeded in stages (Figure 1). Alternative models were compared at each stage. The maximal transcription rates, mRNA degradation rates and other biochemical parameters were estimated by fitting the models to quantitative, molecular timeseries data (see supplemental data), as none of these parameter values have been measured experimentally. The consistency of the available data sets enabled this approach. There was little data for key proteins in wild-type plants, so our initial models were based on quantitative mRNA expression patterns, with indirect information on CO protein levels and their regulation by light. Twenty-four sets of timeseries data (supplemental table 1) were selected to construct and validate the models (see supplemental data).

Model 1: activation of FT by CO and light

Model 1 aimed to simulate the accumulation of FT mRNA, starting from CO mRNA expression data. The detailed mechanism of FT activation by CO protein remains to be determined, so several models were tested (supplemental figure 1, supplemental data). In the simplest model (1a), we assumed that the CO protein was produced rapidly and was highly unstable, so that accumulation of the CO protein mirrored CO mRNA. Furthermore we supposed that the CO protein was only active in the light. Thus the rate of FT transcription was determined by the level of CO mRNA when light was present and FT was not transcribed in darkness. Parameter values for this model were estimated using data on CO and FT mRNA levels in wild-type plants grown under long and short photoperiods (sets 1, 3, 8 and 9, see supplemental table 1), quantified from two publications of the Kay laboratory (Imaizumi et al., 2003; Yanovsky and Kay, 2002). We term these the training data (Figure 2). As expected, a limited number of parameter values allowed accurate simulation of the observed pattern of FT mRNA accumulation (see supplemental text). Using the optimal parameter sets, the fit of simulated FT mRNA levels to either training data set was better than the fit of the experimental data sets to each other, indicating that no better match to the training data was possible.

A more complex model (1b) explicitly included an unstable CO protein that was stabilised during the light interval but rapidly degraded in darkness. Light-driven accumulation of this protein promoted FT transcription. Model 1b also fitted well to the training data, with no significant improvement over model 1a (unpublished results). More complex models, involving for example an additional effect of light on the ability of the CO protein to activate FT transcription, failed to improve the fit (see

supplemental data). Models 1a and 1b were validated using further sets of *CO* and *FT* mRNA data from a variety of photoperiodic conditions. The parameters developed for the training data also fitted the validation data well (supplemental figure 1C; supplemental text), indicating that the simple mechanisms of submodels 1a and 1b recapitulated the overall activation of *FT* by *CO*. As model 1b explicitly includes regulation of the CO protein, we anticipate that this will be more useful for comparison to future molecular data.

Modification of FT activation

The quantitative models allowed us to test whether FT activation was altered in mutant backgrounds. The toc1 mutation, for example, shortens the period of the circadian clock from 24h to 21h. toc1 mutant plants are induced to flower rapidly under 8L:16D, but this defect in photoperiodism can be rescued by growing the mutants under 21h light-dark cycles. It was therefore proposed that the altered circadian clock function is the only photoperiod-response defect in the toc1 mutant (Yanovsky and Kay, 2002). From the CO mRNA levels observed in toc1 mutants, models 1a and 1b simulated levels of FT mRNA that only slightly underestimated the levels observed in toc1 mutants (Supplementary figures 2a-2d and unpublished results). The best match was obtained by increasing the FT activation parameter by 40% (Supplementary figures 2e-2h).

Using model 1a, simulations of *FT* transcription under long days consistently predicted an aberrant peak of *FT* mRNA in the early morning that was absent from the training data (Figure 2b, 2d). The aberrant peak was also predicted using model 1b but was delayed by the time required for CO protein to accumulate (unpublished results, similar to Figure 3d). This defect suggested that our models overlooked an

additional aspect of FT regulation. The effect of CO on FT transcription may be "gated", such that accumulation of CO mRNA in the morning results in less transcription of FT than an equal amount of CO mRNA in the afternoon. We estimated the effect of the hypothetical "morning gate" in model 1a and found that it was photoperiod-dependent but modest (~60% reduction in FT activation; see supplementary text, supplementary figure 3). However, the RNA data available have insufficient time resolution to constrain the effect accurately, and including the morning gate made only a small contribution to the overall fit under standard longand short-day conditions. For these pragmatic reasons and considering additional experimental evidence (see Discussion), no separate "morning gate" mechanism was included in subsequent models.

Model 2: Circadian regulation of CO transcription

The waveform of *CO* mRNA accumulation is thought to be a crucial component of the photoperiod sensor. To include rhythmic *CO* regulation in model 2, we assumed that *CO* was similar to the clock component *TOC1*, which is expressed at the same phase (Locke et al., 2006; Locke et al., 2005b). We therefore simulated *CO* expression based on the *TOC1* component of existing models for the circadian clock. Two clock models were tested. The simplest, in Model 2a, comprised a single transcriptional feedback loop and a single mechanism of light input at dawn (Figure 1) (Locke et al., 2005a). The entrained phase of this clock model is locked to dawn and the remainder of the photoperiod has no effect (Locke et al., 2006). This model fitted *CO* RNA data poorly, because it could not accommodate the observed change in the *CO* waveform between short and long photoperiods (Figure 2). In contrast, the circadian clock in Model 2b comprised two interlocking feedback loops and was entrained through light inputs to two genes (Figure 1) (Locke et al., 2005b). The

interlocking-loop clock model is capable of adjusting its phase relative to dawn in response to varying photoperiods (Locke et al., 2006), resulting in a better fit to *CO* mRNA expression (Figures 3a, 3b).

Model 2b failed to predict the shoulder of CO mRNA accumulation that is observed at the end of the light interval under long photoperiod cycles in wild-type plants (Figure 3b, arrow). The simulated CO waveforms were closer to data from fkf1 mutant plants. Since FKF1 is known to affect CO mRNA accumulation at the end of a long day (Imaizumi et al., 2005; Imaizumi et al., 2003; Sawa et al., 2007), the absence of FKF1 in our model might account for this discrepancy. Under short days, where there is little difference between CO waveforms in wild-type and fkf1 mutants, the model fitted both well. A preliminary model 3F1 was developed to simulate the effect of FKF1 on CO transcription, using data on the FKF1 protein profile to control additional synthesis of CO mRNA in a light-dependent manner (see supplementary text, supplementary figure 4). The model fitted one to two timepoints in the shoulder of CO mRNA data, which had a limited effect on FT mRNA accumulation. Simulating an fkf1 mutation in preliminary model 3F1 caused only a 35% reduction in FT transcription rate at the end of a long photoperiod. Activation of CO transcription by FKF1 in our model represents the double-negative mechanism, in which the CYCLING DOF FACTOR (CDF) repressor proteins are degraded by FKF1, but allows a much simpler mathematical formulation. When further quantified data become available, it should be possible to model recently-discovered details of the molecular mechanisms involved (Fornara et al., 2009; Sawa et al., 2007).

Model 3: Photoperiodic regulation of FT

In order to simulate the regulation of *FT* under the control of light and the circadian clock, submodel 1b was combined with submodel 2b to form model 3 (Figure 1; see supplementary text). This model replaced the experimental *CO* mRNA data used in Figure 2 with the simulated *CO* mRNA waveforms shown in Figures 3a, 3b. Importantly, the model parameters were not altered, because each submodel had already been constrained to the relevant data.

The FT expression patterns predicted by model 3 remained consistent with the FT data from the training and validation data sets (Figures 3c, 3d; Supplementary Figure 1d). The CO mRNA profile simulated by model 2b lacked the FKF1-dependent shoulder at the end of the long photoperiod (Figure 3b), whereas model 1b had matched the FT mRNA based on data that included this shoulder. We therefore expected that using the simulated CO mRNA profile in model 3 would yield lower levels of simulated FT mRNA, compared to model 1b. A CO mRNA profile similar to an fkf1 mutant might simply have yielded the low levels of FT mRNA that had been observed in fkf1 mutant plants. The peak level of simulated FT mRNA in model 3 was indeed lower than observed in wild-type plants but, surprisingly, the reduction was only 40% (Figure 3d), which was an overestimate of an order of magnitude compared to the FT RNA levels observed in the fkf1 mutant. Thus model 3 simulated a CO mRNA profile similar to the fkf1 mutant but greatly overestimated the FT mRNA level. Removing *FKF1* in the mutant plant caused a much more severe reduction of FT mRNA levels than could be predicted from the effect of the fkf1 mutation on CO mRNA levels alone. Consistent with this, adding the FKF1-dependent shoulder to the CO mRNA profile in preliminary model 3F1 had predicted only a modest increase in

FT mRNA levels (supplementary figure 4). Together, these results indicated that a major effect of FKF1 may be to activate FT expression downstream or independently of CO mRNA.

To estimate the importance of *FKF1*-dependent activation for *FT* transcription, we constructed a speculative model (model 3F2), in which the observed FKF1 protein profile and the simulated CO protein together promoted *FT* transcription (see supplementary text). The model was matched to the training data sets (8 and 9; see supplementary table 1) that allowed direct comparison of wild-type and *fkf1* mutant results (Figure 4). The new *CO* mRNA profiles were matched to the data for wild-type and *fkf1* mutant plants under long photoperiods, including the *FKF1*-dependent shoulder in the wild type (Figures 4c, 4e). The model predicted a smaller effect of *FKF1* on *CO* RNA under short photoperiods, consistent with the data (Figure 4b). Simulated *FT* mRNA levels showed an improved profile in wild type (Figure 4e). The aberrant morning peak of earlier models (Figures 2b, 2d) was removed, because FKF1 levels are low at dawn (Supplementary Figure 4a). Simulations with model 3F2 showed that 90% of wild-type *FT* transcription at the end of a long photoperiod was FKF1-dependent.

The photoperiod-dependence of this effect was similar to the effect of FKF1 on *CO* transcription. This raised the possibility that CO and FKF1 cooperate to regulate both *CO* and *FT* transcription by a single mechanism, which would include a positive feedback of CO protein upon *CO* mRNA abundance (Figure 4j). To test this hypothesis, the FKF1-dependent shoulder of *CO* mRNA under long photoperiods was measured in wild type plants and in seven mutant lines carrying *co* alleles that

severely affect flowering time (Supplementary Figure 7). Control *fkf1* mutant plants showed low *CO* mRNA levels 13h after dawn (about 25% of wild-type levels), consistent with Figure 4. *CO* mRNA was undetectable in one insertional mutant *co* allele. The other six alleles had *CO* mRNA levels very close to wild type, showing that CO protein function was not required for the FKF1-dependent shoulder in *CO* transcription. These data favor the model depicted in Figure 4a, in which FKF1 has two distinct effects: its known regulation of *CO* mRNA levels, which does not require CO protein, and a previously-undescribed effect on *FT* expression, which depends on CO.

We next explored the qualitative patterns of FT regulation in response to a range of different light-dark cycles. As the FKF1 protein profiles required for model 3F2 were available for only two conditions, these simulations used model 3. FT mRNA levels increased in a non-linear fashion when the system was stably entrained to 24h light-dark cycles with longer photoperiods (Figure 5a). Treating a short-day-entrained system with one longer photoperiod had a more graded effect (Supplementary Figure 5), indicating that circadian entrainment significantly affected the photoperiod response (see Discussion). Data to inform the component models were only available for a limited range of conditions, so it was not unexpected that the clock model did not entrain stably to some exotic light-dark cycles. The model remained strongly rhythmic in these conditions but phase variations between successive cycles indicated that it was not following a stable, entrained limit cycle, which was the condition imposed for our analysis (see Supplemental Data). Nonetheless, two patterns of FT regulation appeared physiologically relevant (Figure 5a). Firstly, light-dark cycles of longer or shorter duration than 24h partially activated FT under all photoperiods and,

secondly, the steepest increase of *FT* expression with photoperiod occurred under 24h cycles. Thus the model predicts that there will be an optimal cycle duration to obtain the strongest photoperiodic switch, likely in a 24 h environment.

Model 4: Prediction of flowering time

Published flowering time data differ widely among Arabidopsis accessions and across laboratories, reflecting the many environmental inputs that control absolute flowering time (Boss et al., 2004). Most molecular studies, moreover, have focused on one standard long and short photoperiod condition, so the non-linear relationship between the FT mRNA profile and flowering time could not be estimated from the data available (see supplementary text). We therefore compared flowering time data to the FT expression profiles predicted by model 3, where we could perform simulations for any photoperiod. Simple mathematical functions fitted well to flowering data for plants of the Columbia accession (Corbesier et al., 1996), with clear differences in the functions required for different experimental protocols (see supplementary text, and supplementary figure 6). A sigmoid function matched data sets from three laboratories that used similar experimental protocols: data on days to flowering in plants of the Columbia accession (Supplementary Figure 6a, Corbesier et al., 1996) and data on total leaf numbers for plants of the Landsberg(erecta) accession (Figure 5b, Wilczek et al., 2009) and the Wassilewskija accession (Figure 5c, Pouteau et al., 2008). The critical photoperiod that elicited the half-maximal flowering response was almost identical in Figures 5b and 5c, despite the differences in absolute leaf numbers (see supplementary information). Mutation of CO prevents FT expression in the models, so co mutant plants are predicted to flower under all photoperiods with the same, high leaf number as wild-type plants under very short photoperiods, as confirmed in the

recent data (Wilczek et al., 2009). The flowering function offers a standard approach to reveal robust behaviour of the photoperiod response system.

Discussion

The external coincidence model can clearly provide a workable photoperiod sensor (Carré et al., 2006). We aimed for a more detailed, quantitative explanation of the observed molecular regulation that could be linked to the whole-organism response. Our approach will be validated if the resulting models accurately predict the molecular data yet remain comprehensible, if the models direct future experimentation to address gaps in current data, and if the models give insight into comparable processes in other contexts. The data required need not present technical challenges. Consistent data sets for *CO* and *FT* mRNA levels and flowering times would already be valuable to explore a wider range of environmental conditions and genotypes with the full range of *FT* profiles, from *ft* mutants to *FT*-overexpressing lines. These data would test the simple functions assumed here for CO protein synthesis and for the effectiveness of FT as a floral inducer. Current data were sufficient to make eight specific, testable predictions (Supplementary Table 2), which are discussed below, together with their functional implications for photoperiod responses.

Suppressed induction of FT in the morning

A good overall fit after parameter optimisation shows that a model is consistent with the molecular data. The simplest models of FT activation by light and CO were largely sufficient to recapitulate the molecular data. Simulating data from the toc1 mutant confirmed that this mutation in the circadian clock affected FT regulation largely by altering rhythmic CO mRNA expression (Niwa et al., 2007; Yanovsky and

Kay, 2002), though a small (~40%) increase in FT activation by another mechanism remains possible (prediction 2, supplementary table 2). A specific failure of the model can be more informative. For example, the overestimation of FT levels at the start of a long photoperiod (Figure 2) suggested that another level of regulation reduces the effectiveness of CO at this time (prediction 1 in supplemental table). A similar, morning-specific suppression has been identified in experimental studies of COoverexpressing plants (Valverde et al., 2004) and linked to phyB in *cop1* mutant plants (Jang et al., 2008). Our models show that this mechanism operates in wild-type plants, quantify its effects, show that the effect is greater in long than in short photoperiods (Supplementary Figure 3), and suggest a molecular mechanism (Figure 4; see below). The quantitative effect of the suppression was modest (~60% reduction in FT activation in Supplementary Figure 3) and its parameters were not well constrained, because it only affected one to two data points in the FT profile. Moreover, morning expression of FT can sometimes be observed experimentally (Corbesier et al., 2007), and flowering can be accelerated under exotic light cycles that drive high CO expression in the morning (Roden et al., 2002). Thus the morning suppression mechanism is not always effective at the level of FT expression and is not always relevant at the level of flowering time, though it is apparent in most of the molecular data sets considered here. Regulation by FKF1 provides a parsimonious mechanism for the suppressive effect, as detailed below.

Regulation of CO by a photoperiod-responsive clock

The circadian peak of *CO* RNA accumulation moves to a later phase under long photoperiods (Figure 2). The interlocking, dual feed-back loop model of the clock was required to match this phase delay (Figure 3, prediction 3 in supplemental table), because the phase of this clock model responds strongly to light at dusk (Locke et al.,

2006). A more complex, three-loop clock model (Locke et al., 2006) matches better to data for circadian-regulated genes other than CO, where peak phase is much less delayed under long photoperiods (Edwards et al, unpublished results, Millar and Kay, 1996). The CO entrainment profile is consistent with the two-loop model and therefore might reflect a distinct circadian clock mechanism that is restricted to specific cell types, for example in the vasculature (An et al., 2004). Circadian clocks with distinct entrainment patterns have also been proposed in the photoperiod sensor of the short-day plant, *Ipomoea nil* (Hayama et al., 2007). The unknown mechanism that regulates some aspects of the CO waveform independently of the GI rhythm (Fornara et al., 2009) might also be consistent with the unusual photoperiod-sensitivity of the timing of peak CO RNA.

The dusk-sensitive entrainment of *CO* makes the system more responsive to lengthening photoperiods, particularly to delays in lights-off, than it is to stable, long photoperiods. The sensitivity to photoperiod change arises because the first lengthened photoperiod simply allows a longer duration of light to coincide with a *CO* mRNA rhythm that is set to the early phase characteristic of a short day, as proposed by Bünning's external coincidence mechanism (Bünning, 1936). Under stable, long photoperiods, however, the observed phase of the *CO* rhythm is delayed, moving more of the *CO* mRNA peak into the dark interval. After entrainment to 8h photoperiods, for example, model 3 predicted a significantly greater *FT* area on the first 10h or 12h photoperiod than it did when stably entrained to 10h or 12h photoperiods (supplemental figure 5). The circadian entrainment of *CO* is consistent with observed flowering responses to changes in the time of sunset, which have evolved exquisite sensitivity in tropical trees (Borchert et al., 2005).

Regulation of CO and FT by FKF1 and photoperiod

Whereas circadian entrainment delays *CO* expression under longer photoperiods, *FKF1* promotes earlier *CO* mRNA accumulation (reviewed in Imaizumi and Kay, 2006). The *FKF1*-dependent shoulder in *CO* RNA accumulation was readily simulated by adding a second source of *CO* RNA to supplement the waveform driven only by the clock model (Figures 3 and 4, supplemental figure 4). This source could be either an arbitrary square waveform (data not shown) or the observed FKF1 protein profile, which also has a sharp onset and decline (Imaizumi et al., 2003). In either case, the sharp change in the additional *CO* was important to match the dip in *CO* RNA profile that is often observed at the end of a long photoperiod (prediction 5).

Our models (Figure 3, Figure 4) highlighted a dramatic and previously unsuspected effect of *FKF1*, to promote *FT* expression independently of its effect on *CO* RNA accumulation (prediction 6). For an intuitive illustration, consider that the levels of *CO* mRNA in the light are comparable or higher in *fkf1* mutants under long photoperiods compared to the wild type under short photoperiods (compare Figure 3b with 3a), yet the cognate *FT* mRNA levels are much lower in the mutants (Figures 3c, 3d). Direct interaction of FKF1 with CO protein might enhance CO function (Fukamatsu et al., 2005), providing a mechanism based on known components. Light-stabilised CO protein would then activate *FT* transcription in an FKF1-dependent manner. This was achieved in a revised model by using the FKF1 protein profile to drive the transcription of *FT* in addition to its effect on *CO* (model 3F2, see supplemental text). This speculative model matched wild-type *FT* mRNA waveforms well and lacked the morning-specific peak of FT expression observed with earlier models (Figure 4). As *FKF1* is not expressed in the morning, simulated *FT* mRNA

expression remains low at this time even if *CO* RNA is present. Thus the postulated function of *FKF1* provides a parsimonious molecular mechanism for the morning "gate" (prediction 1). Constitutive expression of *FKF1* and *GI* was insufficient to activate *FT* expression immediately after dawn (Sawa et al., 2007), however, indicating that further analysis of the morning "gate" is warranted. FKF1 was estimated to increase *FT* transcription 10-fold in our model compared to the *fkf1* mutant, highlighting the importance of FKF1 as a photoperiodic regulator (Imaizumi and Kay, 2006). FKF1 increased *CO* transcription by only 35%, suggesting that FKF1-independent factors are also important in regulating *CO* mRNA levels (Fornara et al., 2009; Imaizumi et al., 2005).

The relationship between the two effects of *FKF1*, on *CO* and *FT*, is unclear. A possible extension to model 3F2 was to propose that FKF1 functioned together with CO protein, and that this mechanism activated both *FT* and *CO* transcription (prediction 7). This parsimonious hypothesis predicted that CO protein would be required for the *FKF1*-dependent shoulder of *CO* mRNA under long photoperiods. New experimental data for the *CO* mRNA levels of seven *co* mutant alleles failed to support this notion (Supplemental figure 7). Our results therefore predict that *FKF1* functions differently to regulate *CO* and *FT*, indicating that a novel regulatory mechanism is involved in the control of *FT*. It is possible that this function is *GI*-dependent, as *GI* regulates flowering *via* the circadian expression of *CO* (as in our models) but also by a genetically-separable mechanism (Gould et al., 2006; Mizoguchi et al., 2005).

Tuning the mechanisms of daylength perception

The circadian clock models entrained stably to a limited range of exotic light-dark cycles with total durations that varied from 24h (Figure 5). The models were developed using data from only constant conditions and 12L:12D cycles (Locke et al., 2005a; Locke et al., 2005b), so more flexible models might be constructed based upon new data on the clock components under other conditions. The mathematical theory of coupled oscillators (Guckenheimer and Holmes, 1983) shows that stable entrainment occurs when the system parameters are within an area of parameter space described as the Arnold tongue. Changing the period of the entraining cycle significantly away from the period of the oscillator moves the system outside the Arnold tongue. Consistent with theory, the clock model then becomes quasi-periodic, as also reported for circadian rhythms in many species.

Using model simulations, we predicted that discrimination between long and short light intervals will be greatest when the total duration of the entraining cycle is 24h (Figure 5; prediction 8). This qualitative prediction is reminiscent of the classic experiments on soybean (Hamner and Takimoto, 1964) and matches more detailed data from the hamster, where photoperiodic regulation of the reproductive system also showed the greatest amplitude under 24h cycles (Elliott, 1974). This effect also can be related to the theory of coupled oscillators (Guckenheimer and Holmes, 1983). Altering the duration of the entraining cycle by a moderate amount relative to the period of the oscillator moves the system within the Arnold tongue, and alters the phases of the clock components. The circadian clock is presumed to be adapted to the 24h entraining cycles in which it has evolved: the clock components (and outputs such as *CO*) will be regulated with peak phases that are physiologically optimal

(Pittendrigh and Daan, 1976). Changing the duration of the entraining cycle will alter their phases and lead to a suboptimal response, either slowing growth (Dodd et al., 2005), or in this case weakening the photoperiodic sensor.

Our models illustrate how the external coincidence mechanism has evolved in Arabidopsis to a more elaborate form than Bünning's original hypothesis. CO protein was the first molecular correlate of photoperiod to be identified and its dual regulation by the clock (transcriptionally) and by light (post-translationally) forms an external coincidence detector. The photoperiod-sensitive entrainment of the CO mRNA rhythm extends beyond the simplest external coincidence hypothesis and has potential functional significance in detecting photoperiod change, but may require specialized circadian timing, as discussed above. FKF1 forms a second external coincidence detector that regulates CO mRNA (Imaizumi et al., 2003) and we show that it is crucial in activating FT (prediction 6). As CO and FKF1 function together to regulate FT at the end of the photoperiod, separating their expression in time might in principle be sufficient to prevent flower induction under short photoperiods, as proposed by the internal coincidence hypothesis (Pittendrigh, 1960). It will be interesting to determine whether the entrainment of their circadian rhythms (and the rhythms of other clock-controlled regulators) responds differently to photoperiods, as this would be required to introduce an aspect of internal coincidence (as implied in Imaizumi and Kay, 2006). In contrast, another photoperiodic mechanism appears to control the degradation rate of cry2 protein at the start of the day (El-Din El-Assal et al., 2001). The effect of cry2 degradation on photoperiodism is unclear, and our current models match FT mRNA profiles without this modulation of light input.

The existence of multiple photoperiod sensors has important consequences for understanding plant physiology. Firstly, it greatly increases the potential for specialized photoperiodic sensors to control different physiological responses within a single species, including responses of vegetative organs. Secondly, it is unclear which (or how many) of the molecular mechanisms will be conserved across species with similar photoperiodic responses. Finally, it increases the possibility that species with different photoperiodic responses might differ radically in their molecular mechanisms. It is therefore all the more striking that homologues of CO and FT have been implicated in the short-day photoperiodic response of the dicots *Ipomoea nil* (Hayama et al., 2007) and poplar (Bohlenius et al., 2006) and of the monocot rice (the genes Hd1 and Hd3a, respectively, reviewed in Hayama and Coupland, 2004; Izawa, 2007). The profile of *Hd1* RNA strongly resembles that of *CO* (supplemental Figure 8a), such that Hayama et al. (Hayama et al., 2003) proposed that a single change of sign, equivalent to making CO a negative regulator of FT, would be sufficient to convert the long-day response of Arabidopsis to the short-day response of rice. Using RNA profiles of *Hd1* and *Hd3a* under long and short photoperiods, we constructed the simplest model of the rice photoperiod sensor based upon our Arabidopsis models (see supplemental data). The proposed repressive function of *Hd1* could fully account for the photoperiodic regulation of the mean level of Hd3a, because the coincidence of light with Hd1 RNA in the evening changes significantly between long and short photoperiods. There is, however, little or no difference in Hd3a expression in the evening, so coincidence does not directly explain the temporal profile. Peak Hd3a expression occurs in the morning (supplemental figure 8b), and matching this timing required a separate (and unknown) clock-regulated factor distinct from the Hd1 repressor. It will be interesting to determine how the morning-specific photoperiodic

regulator of *Hd3a* relates to the well-described, evening-specific regulators in Arabidopsis. There are now several possible candidates in rice (reviewed in Hayama and Coupland 2004; Izawa 2007). Recent data gives this added relevance for Arabidopsis, because *FT* can also be expressed in the morning in some conditions (Corbesier et al., 2007), suggesting that the rice regulatory mechanism might also be present in Arabidopsis.

The photoperiodic switch is part of a broader network of developmental pathways and environmental responses that control the flowering of Arabidopsis (Boss et al., 2004). Models of this broad network (Welch et al., 2003) have the exciting potential to link our detailed molecular mechanisms to larger-scale phenological models. These already have widespread applications in crop scheduling and crop improvement (Adams et al., 2001; Hammer et al., 2006) and have been successfully applied to Arabidopsis development (Wilczek et al., 2009).

Experimental procedures

Plant growth and RNA assays

Seeds of *fkf1*, the *co* alleles and cognate wild types were generously supplied by G. Coupland (Koeln) or by the Nottingham Arabidopsis Stock Centre. Plants were grown as described (Locke et al., 2005b) under 16L:8D for 10 days at 22°C. Samples were harvested 13h after lights-on; RNA was extracted and analysed by qRT-PCR as described (Locke et al., 2005b).

Computational methods

Quantitative expression profiles for CO and FT mRNA under various conditions were digitised from charts or graphs in the literature or kindly provided by the original authors (see supplemental data). Timeseries data were numbered (see supplemental table 1), normalized and checked for consistency (see supplemental data). Twentyeight timeseries from wild-type plants were used for most model training and validation, with ten further timeseries from toc1 and fkf1 mutants. Models were constructed as ordinary differential equations in Matlab (Mathworks, Cambridge UK); SBML versions will be available from the Biomodels repository upon publication (Le Novere et al., 2006), and in versions compatible with the Circadian Modelling simulation interface (available at www.amillar.org/Downloads.htm). Model equations and parameters are presented in the supplemental data. Parameters were estimated by fitting to the relevant data (for the wild type, to the training data sets 1, 3, 8, 9; see supplemental table 1), using a boundary value solver to ensure that the model produced stable, limit cycle solutions (see supplemental data). Models 3F1 and 3F2 including FKF1 function are described as speculative, because there is much less quantitative timeseries data available for FKF1 in the literature than for CO and FT.

We test these models only in 8L:16D and 16L:8D conditions, where FKF1 data are available.

Acknowledgements

AJM gratefully acknowledges helpful discussions with Carl Johnson, Steve Welch and Peter Crawford, and the hospitality of Luis Serrano and the Centre de Regulació Genòmica, Barcelona during revision of the manuscript. This work was supported by BBSRC award BEP17427 to AJM, DAR and IAC, and by BBSRC/EPSRC SABR award F0052371 to KJH, AJM, DAR and others. JCWL was supported by a Sainsbury Postgraduate Scholarship from the Gatsby Charitable Trust. TS is supported by a Postgraduate Scholarship from the Royal Thai Government. DAR holds an EPSRC Senior Fellowship and is supported by EU BioSim Network Contract 005137. The Centre for Systems Biology at Edinburgh is a Centre for Integrative Systems Biology supported by BBSRC and EPSRC award D019621.

Figure legends

Figure 1. Overview of modeling stages.

measurement in Arabidopsis. Nature 419, 308-312.

Model 1 uses *CO* mRNA data and light/dark cycles as inputs and simulates *FT* mRNA accumulation. In model 1a, light and *CO* mRNA activate *FT* transcription whereas in model 1b light inhibits the degradation of CO protein, which activates *FT*. Model 2 takes a light/dark cycle as input and simulates the rhythmic expression of *CO* mRNA. Model 2a is based on a single-loop model for the circadian clock (Locke et al., 2005a) while model 2b uses the interlocking-loop model (Locke et al., 2005b). Models 1 and 2 are combined in model 3a, which simulates *FT* mRNA profiles for a given light/dark cycle. Speculative models including *FKF1* are presented in Figure 4 and Supplemental Figures 4, 5 and 8. Model 4 uses model 3 to predict flowering responses based on *FT* mRNA accumulation.

Figure 2. External coincidence of *CO* and light predicts *FT* mRNA expression.

FT mRNA expression patterns were simulated using model 1a, based on the training data sets (A, B, Yanovsky and Kay, 2002) and (C, D, Imaizumi et al., 2003), under short-day (A, C) and long-day (B, D) conditions. The maximal CO mRNA level under short days is set to 1 for each set of data and simulations. Open circles, CO mRNA data; closed circles, FT mRNA data; solid line, simulated FT mRNA levels. Filled bar on time axis, dark interval; open bar, light interval.

Figure 3. Model 3 recapitulates *CO* mRNA profiles of *fkf1* mutant plants, but predicts *FT* mRNA close to wild type.

Expression patterns of *CO* mRNA (A, B) and *FT* mRNA (C, D) were simulated using model 3 (solid lines), under short-day (A, C) and long-day (B, D) conditions. The arrow in B marks the *FKF1*-dependent shoulder in *CO* expression, which is absent in the model. Expression level data (sets 8 and 9, Supplementary Table 1, Imaizumi et al., 2003) are shown, as in Figure 2. Open symbols, *CO* mRNA data; filled symbols, *FT* mRNA data; circles, data from wild type; squares, data from *fkf1* mutant. Filled bar on time axis, dark interval; open bar, light interval.

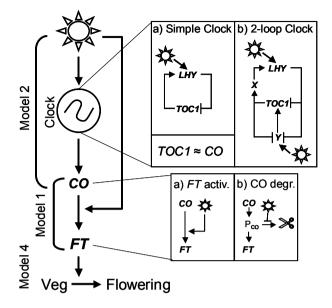

Figure 4. *FKF1* affects *FT* activation.

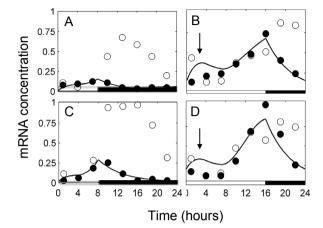

Speculative model 3F2 (A) includes light-dependent activation of both *CO* and *FT* by *FKF1*. Simulations (solid lines) can closely match the expression patterns (Imaizumi et al., 2003) of *CO* (B, C, F, G) and *FT* (D, E, H, I) mRNA in both the wild type (B-E) and *fkf1* mutant (F-I) under short-day (B, D, F, H) and long-day (C, E, G, I) conditions. An alternative, more parsimonious hypothesis is shown in (J): *FKF1* has a single effect on CO protein activity, which both controls *FT* transcription and feeds back positively to regulate *CO* transcription (see Supplemental Figure 7). Open

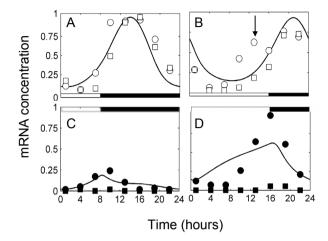

symbols, *CO* mRNA data; filled symbols, *FT* mRNA data; circles, data from wild type; squares, data from *fkf1* mutant. Filled bar on time axis, dark interval; open bar, light interval.

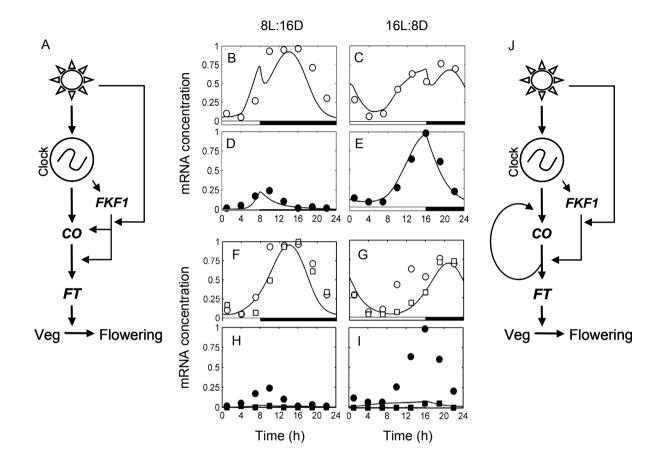

Figure 5. A photoperiod sensor for 24h days, regulating flowering.

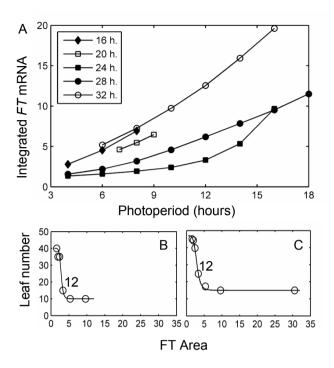

(A) *FT* expression was simulated under light-dark cycles comprising 6h – 16h photoperiod in a total cycle duration of 16h (diamonds) to 32h (open circles), using model 3. 24h cycles show the largest ratio of integrated *FT* mRNA between long and short photoperiods. Absent results are due to unstable circadian entrainment in some conditions. (B and C) The integrated *FT* mRNA area simulated by model 3 under different photoperiods (diamonds) is related to flowering time data for the same photoperiods by a simple function (line), with specific parameter values (see supplemental text) for data sets from Landsberg(*erecta*) (B, Wilczek et al., 2009) and Wassilewskija (C, Pouteau et al., 2008). Flowering time data covered photoperiods from 6L:18D to 16L:8D in (B) and (C), with an additional data point for constant light in (C). The data point for 12L:12D is labelled (12).

Supplemental Data

Data Collection and Analysis

Numerical values for *CO* and *FT* mRNA expression patterns were captured by digitising published charts or graphs of quantified data, or were kindly provided by the original authors (Supplemental Table 1). Experiments are numbered; pairs of *CO* and *FT* waveforms collected in the same genotype and experiment are given the same number. The data include some variation in experimental details but share a similar basic design. In particular, wild-type plants under short photoperiods (8L:16D) and long photoperiods (16L:8D) were tested in 3 and 7 experiments, respectively, with more limited representation of exotic, non-24h cycles. Several Arabidopsis accessions were tested, as well as *fkf1* or *toc1* mutants and *CO*-overexpression lines. RNA levels were measured using RT-PCR in all cases, with detection either by real-time fluorescence labelling or by hybridisation of radio-labelled probes. The mRNA used as a constitutive control for inter-sample normalization varied. Primers that amplify *UBIQUITIN* (*UBQ*) transcripts (Blazquez and Weigel, 1999) were used in experiments 1-12 and similar primers (Cerdan and Chory, 2003) for experiments 13 and 14. Experiment 15 (Somers et al., 2004) used *ACTIN2* (*ACT2*). In one experiment, the ratio *FT/CO* was quantified directly (Valverde et al., 2004).

As a preliminary comparison between experiments, the ratio of peak FT to CO levels was calculated to determine whether these different waveforms were mutually compatible (data not shown). There is potential for significant variation in some experimental methods, for example the specific radioactivity of the probes used in the hybridization experiments might vary as a function of their age. The ratio (peak FT / peak CO) fell in a range 0.13 to 1.3, with the exception of experiments 11 (ratio = 3.3), where radiolabelling was used, and 15 (ratio = 6.4), possibly related to the ACT2 control. Waveform 12 had by some distance the lowest ratio (0.15) of any experiment in a long photoperiod. The FT waveform ftcoox1 in the CO-over-expression experiment of (Suarez-Lopez et al., 2001) lacks comparable information on

the CO mRNA. In contrast, the other FT data from CO-over-expression lines, coox2 and coox3, are normalized to the level of CO mRNA (Valverde et al., 2004). For these reasons, the data of (Suarez-Lopez et al., 2001) and (Somers et al., 2004) were not considered further.

Data analysis and normalisation for modelling

The remaining data were tested for comparability. According to the simplest formulation of the external coincidence hypothesis in Arabidopsis, FT expression should be related to the integrated area under the curve of CO mRNA accumulation that coincides with light. The set of selected data was tested against this hypothesis, to confirm that pooling results from diverse sources did not obscure interpretation of the data. This entails comparisons across experiments that might use different experimental control transcripts for technical standardization. The data for all genes and photoperiods within each experiment were therefore normalized to a common internal standard, the maximum level of CO mRNA in wild-type plants under short (8L:16D) photoperiods. CO mRNA has a broad, flat-topped waveform in these conditions, which reduces the variability due to the particular timepoint chosen for sampling in different experiments. Integrated areas were calculated under the CO mRNA curve during the light interval only, and under the FT mRNA curve over a full cycle. The FT area is clearly positively correlated with the CO area that coincides with light, across all the data sets (supplemental figure 1A). Variation among experiments accounted for less than a 2-fold range in the FT areas under conditions that gave similar CO areas. As an additional test, the normalized FT area was plotted against the duration of light in each cycle (Supplemental figure 1B). The correlation was also positive but this result is weaker, because the available data are clustered around 8h light and 16h light with very little data at intermediate photoperiods. Futhermore, the variation in experimental conditions produces clear outliers, for example from experiment 6 (10L:20D).

To take account of some of the variability, two different short day (SD) and long day (LD) experiments were used in the initial estimation of the model parameters (the training data

sets): experiments 1 and 9 (short photoperiods), 3 and 8 (long photoperiods). These were produced by the Kay laboratory (Imaizumi et al., 2003; Yanovsky and Kay, 2002), and allowed direct comparison between these wild-type waveforms used to develop the models and the *toc1* and *fkf1* mutant waveforms that were tested in the same experiments.

In order to compare model simulations to the experimental waveforms, the simulations were normalized to the maximum of *CO* mRNA under SD. Simulations were normalized by dividing the *CO* and *FT* waveforms in SD and LD by the maximum of the simulated *CO* waveform of the wild type in SD, then multiplying them by the maximum of the experimental *CO* waveform in SD. In this way, the simulated and experimental *CO* waveforms in SD share the same upper limit (Figure 3). This procedure is unnecessary for models 1a and 1b, which take their normalization directly from the size of the experimental *CO* waveform (Figure 2).

Model Testing Procedure

The kinetic parameters required in the model equations have not been directly measured by experiment. Random parameter sets (usually over 3,000, with each parameter usually bounded in the range 0 to 100) were therefore evaluated, by testing the fit of the model solution with that parameter set to the training data, using Matlab version 6 (Mathworks, Cambridge, UK). The model was solved for 120 hours (five 24-hour days) of entrainment under the appropriate light-dark cycle, with a final cycle that was used as the seed for a differential equation boundary value solver (bvp4c, MatLab version 6). The resulting solution was therefore guaranteed to be a true, attracting limit cycle. After using the scaling described in the previous paragraph, the fit of the model to the relevant data set(s) was measured using a weighted mean square method. The weights were chosen to be the maximum of the experimental CO and FT mRNA waveforms in each photocycle (short or long days) to prevent the fitting procedure being dominated by the largest FT mRNA abundance in long days.

The 20 parameter sets with lowest cost (best fit) were typically subject to 5 cycles of 20 iterations of the Nelder-Mead unconstrained simplex optimization method (Matlab version 6). The Nelder-Mead method typically improved the cost values by 20-30%, frequently changing the cost ranking compared to the starting parameter sets. After optimization, the difference in cost values of the 20 best solutions tended to be small, although some parameter values could be widely spread in parameter space.

Models

Our models are based on Michaelis-Menten kinetics. All parameter values are positive, so terms that model the degradation of the relevant molecular species are given negative sign. In the equations below, the term L=1 for light and 0 for darkness. The square waveform of light:dark cycles in growth chamber experiments was simulated using a hyperbolic tangent function to produce abrupt light-dark transitions that are numerically continuous. Throughout, units of time are hours (h); characteristic units for molecular species are nanomoles (nmol); the relative mRNA profiles were normalized to an internal mRNA standard as noted below. For a diagrammatic representation of the different models and their relationships, see Figure 1.

Level 1 – Regulation of FT by the CO concentration observed in data

Model 1a

FT mRNA synthesis is a function of the experimental CO mRNA amount, which is taken to approximate the amount of active CO protein. CO activates FT transcription only in the light (equation 1).

$$\frac{dmFT}{dt} = L \cdot vCO \cdot \frac{eCO}{kCO + eCO} - vFT \frac{mFT}{kFT + mFT} \tag{1}$$

mFT = simulated FT mRNA, vCO = maximum FT transcription rate = 25.9719 nmol/h, kCO = Michaelis constant of FT activation by CO = 70.6788 nmol, eCO = experimental CO mRNA concentration, vFT = max rate of FT mRNA degradation = 12.9543 nmol/h, kFT = Michaelis constant of FT mRNA degradation = 62.2131 nmol.

Model 1b

The experimental CO mRNA amount is translated into CO protein that is degraded only in darkness (2). CO protein activates FT transcription equally in all conditions (3).

$$\frac{dCOp}{dt} = vCOm \cdot eCO - (1 - L) \cdot vCOp \frac{COp}{kCOp + COp}$$
 (2)

COp = simulated CO protein, vCOm = rate constant of CO protein production = 3.3243 nmol/h, eCO = CO mRNA concentration in experimental data, vCOp = maximum rate of CO protein degradation = 10.4291 nmol/h, kCOp = Michaelis constant of CO protein degradation = 1.4977 nmol.

$$\frac{dmFT}{dt} = vCOFT \frac{COp}{kCOFT + COp} - vFT \frac{mFT}{kFT + mFT}$$
(3)

 $vCOFT = \max FT$ transcription rate = 0.4561 nmol/h, kCOFT = constant of activation by CO = 9.9181 nmol, $vFT = \max \text{ rate of } FT \text{ mRNA degradation} = 4.9569$ nmol/h and kFT = Michaelis constant of FT mRNA degradation = 12.3926 nmol.

Either model 1a or 1b could fit well to the experimental data (Supplemental Figure 1c). As model 1b explicitly includes regulation of the CO protein, we anticipate that this will be more useful for comparison to molecular data, and discuss the results from this model in the main text.

The "morning gate"

To reduce the excess FT mRNA predicted in the morning (Figure 2), we inserted new parameters into model 1a that reduced the effectiveness of light in activating FT (by multiplying vCO by a constant value between 0 and 1), for a specified time interval (between 0 and 6 hours) starting at dawn. No single combination of effectiveness and duration parameters allowed an improved fit to the training data under both long days and short days (unpublished results). The data could only be matched by allowing the gating parameters to vary with photoperiod. A good fit was obtained for some parameter sets with no gating at all under short-day conditions. The best fits resulted from a lower gating effect (and/or for a shorter interval) under short photoperiods, combined with stronger gating (and/or for a longer interval) under long photoperiods (Supplemental figure 3 and legend shows one example). The morning gate improved the fit to only one to two data points in the available FT RNA timeseries, making a relatively small contribution to the overall fit. By the same token, the time resolution of the current data provides insufficient constraints to parameterise the effect accurately. Moreover, several experimental results indicate that the gate is not always effective at the molecular level, nor functionally relevant for flowering (see Discussion). No separate morning gate mechanism was included in subsequent models.

Level 2 – Regulation of CO mRNA by the circadian clock

Model 2a

This model is based on the first clock model (Locke et al., 2005a), which consists of two genes, *LHY* and *TOC1*, that form a single negative feedback loop. Light entrains the clock model only by enhancing *LHY* transcription, so the phase of the clock is locked to lights-on.

The nuclear TOC1 protein concentration from this model peaks at an appropriate phase under short days, and is therefore used without modification as a proxy for CO mRNA.

Model 2b

This model is based on the interlocking-loop clock model (Locke et al., 2005b). This clock model consists of four genes *LHY*, *TOC1* and two unknown genes termed *X* and *Y*, in which *LHY*, *TOC1*, and *X* form one loop, while *TOC1* interacts with *Y* to form a second, interlocking feedback loop. Light activates transcription of *LHY* and also of *Y*. Again, the nuclear TOC1 protein concentration is used as a proxy for *CO* mRNA.

As model 2a clearly failed to fit the phase change relative to lights-on that was observed in the experimental CO data (Figure 2), only model 2b was used subsequently.

Level 3 – Regulation of FT by simulated CO

Model 3

This model combines *CO* simulated using model 2b with the activation of *FT* mRNA simulated using model 1b (equations 2 and 3). Neither model is modified but *nTOC1* replaces *eCO* in equation (2):

$$\frac{dCOp}{dt} = vCOm \cdot nTOC1 - (1 - L) \cdot vCOp \frac{COp}{kCOp + COp}$$
(4)

Parameter values are the same as in (2). *nTOC1* = nuclear TOC1 protein.

Modelling FKF1 effects on CO and FT transcription

Preliminary models were constructed to quantify the effects of *FKF1* upon *CO* and *FT* mRNA profiles. A simple step function gave a good qualitative fit to the shoulder of *CO* mRNA at the end of a long photoperiod (data not shown). As FKF1 protein profiles were quantified by Imaizumi *et al.* (2003) (Supplemental figure 4a), we modelled a more detailed molecular mechanism using these data for 8L:16D and 16L:8D cycles. Our aim here was to fit the *CO*

mRNA waveform in the wild-type plants of one data set as closely as possible, in order to distinguish quantitatively between a possible direct effect of FKF1 on *FT*, compared to an indirect effect of FKF1 on *FT* transcription *via* the regulation of *CO*.

Model 3F1 - FKF1 activation of CO mRNA

The profile of simulated CO mRNA from model 2b (mCO_{TOCI} , originally nuclear TOC1 protein) was modified to fit training data set 8 rather than all four training data sets (Supplemental figure 4b, 4c). As the measured CO mRNA in this data set was greater than the simulated value during the light interval (Figure 3b), a negative term corresponding to a CO mRNA degradation rate was slightly increased (by 0.04% of its original value) during the light interval. All other parameters remained as in model 2b. The increase in CO mRNA due to FKF1 was included as an additional source of CO mRNA (mCO_{FKF1}) using a simple, linear equation (5, see Supplemental figure 4b). The transcription rate is linearly dependent on the observed FKF1 protein level (FKF1) and is active only during the light interval, when L = 1.

$$\frac{dmCO_{FKF1}}{dt} = L \cdot vCO_{FKF1} \cdot FKF1 - vFKF \cdot mCO_{FKF1}$$
(5)

vCOFKF1 = transcriptional activation rate by FKF1 (2 nmol/h), vFKF = mRNA degradation rate (1.8674 nmol/h).

Total *CO* mRNA ($mCO_{TOCI} + mCO_{FKFI}$) closely matched the observed *CO* mRNA profile of data set 8. The additional source of *CO* mRNA briefly increased the simulated wild-type *CO* mRNA profile at the end of the short photoperiod (Figure 4b), consistent with the slight reduction in *CO* mRNA at this time in *fkf1* mutants compared to wild-type plants (Figure 4b). Translating this pool produced CO protein as in (2), and the resulting CO protein activated *FT* as in (3). Under long photoperiods, the increased *CO* mRNA level yielded higher peak *FT* mRNA levels (Supplemental figure 4d), giving a slightly improved match to the *FT* data at 16h compared with the simulation using model 3 (compare with Figure 3d). This effect on *FT* in the wild-type simulation would scarcely justify including the increased complexity of *CO* mRNA regulation but simulations of the *fkf1* mutant were more revealing. In model 3F1, the

FT transcription rate at the end of a long photoperiod (16h after dawn) was only 35% lower in the simulated *fkf1* mutant compared to wild type.

Model 3F2 - Speculative model for FKF1 activation of FT mRNA

The level of FT mRNA observed in fkf1 mutant plants (Figure 3d) was far lower than the prediction from model 3, which lacked FKF1 (Figure 3d), leading us to speculate that FKF1 was also required to activate FT transcription. We modified equation (3) to include the activation of FT transcription by FKF1 protein in the light, giving equation (6), with results shown in Figure 4A. FKF1 activation of FT was implemented as a multiplicative term in (6), because the effect of the fkf1 mutation on FT mRNA levels was much more severe than its effect on CO mRNA. A large proportion of FT mRNA thus becomes FKF1-dependent. For parsimony, we assumed FKF1 was equally effective in regulating CO and FT. Parameter vCOFT was altered compared to (3) to account for the new regulator. New parameters B_{CO} and B_{FKF} were added in order to estimate CO-independent and FKF1-independent FT transcription rates, respectively. These were termed 'basal' transcription rates to indicate that their regulation is unknown, not that it is necessarily unregulated.

$$\frac{dmFT}{dt} = \left(B_{CO} + vCOFT \cdot \frac{COp}{kCOFT + COp}\right) \cdot \left(B_{FKF} + L \cdot vCOFKF1 \cdot FKF1\right) - vFT \cdot \frac{mFT}{kFT + mFT}$$
(6)

vCOFT = max CO-dependent FT transcription rate = 0.58 nmol/h, kCOFT = constant of activation by CO = 9.9181 nmol, B_{CO} = CO-independent transcription rate = 0 nmol/h, B_{FKF} = FKF1-independent transcription rate = 0.22 nmol/h, vCOFKF1 = coupling constant for activation by FKF1 = 2 nmol/h, vFT = mRNA degradation rate = 1.8674 nmol/h, kFT = Michaelis constant of FT mRNA degradation = 5.3925 nmol.

With B_{CO} set to 0, FT transcription remains completely CO-dependent, consistent with undetectable FT levels in the co mutant (Jang et al., 2008; Suarez-Lopez et al., 2001). The parameter is included in the model to reflect the possibility that a small proportion of FT

expression is CO-independent in wild-type plants. Simulations (data not shown) suggested that the upper bound on the parameter value consistent with experimentally undetectable FT mRNA (~5% of wild-type peak level) in the co mutant is about 0.03 (data not shown), 7-fold less than B_{FKF} and 19-fold less than vCOFT. As the numerical value of this very low transcription rate was arbitrary, and it had a negligible effect on FT in wild-type simulations (data not shown), it was set to 0 for parsimony. Future experiments that reliably quantify the low levels of FT RNA in the co mutant may constrain its value above zero.

In order to simulate the *fkf1* mutant, the parameter controlling FKF1's transcriptional effect (*vCOFKF1*) was set to 0 in (5) and (6). The simulated *CO* mRNA profiles (Figure 4f, 4g) were very close to the simulations from model 3, as expected. Reduced *CO* mRNA and protein remained, allowing us to estimate the basal transcription rate of *FT* that was required to produce the small amounts of *FT* mRNA observed in the experimental data on the *fkf1* mutant (Figures 4h, 4i). The net transcription rate at the end of a 16h day was 0.0522 nmol/h in the mutant, compared to 0.5317 nmol/h in wild type. This result emphasizes the large effect of the *fkf1* mutation on *FT* expression, which greatly exceeds the effect expected from the change in *CO* mRNA alone (illustrated by model 3F1, above).

Level 4 – Regulation of flowering time by *FT*

In the final stage of modeling, a direct predictor of flowering time was added to the model. This requires one of the model outputs to be connected to a measure of macroscopic flowering time that corresponds to experimental data (the percentage of plants flowering on a given day, the mean time (days) until flowering or the duration of the vegetative phase (number of leaves) until flowering). There was no suitable data in the literature to define directly the non-linear relationship between the amount of *FT* mRNA and the time to flowering. Such data cannot easily be pooled, as flowering times are highly variable between laboratories and even between experiments. Rather, both variables must be measured for a range of photoperiods in a single experiment. Such data are now urgently required.

In the interim, photoperiod was used as an intermediate variable between the model outputs and the experimental measures of flowering. The level 3 models take photoperiod as an input parameter, so it was possible to predict the relationship between any of the model components and photoperiod. All the flowering measures in the literature are also reported as a function of photoperiod. The level 4 model can therefore be used to interpolate the flowering time for any photoperiod by calibrating the predicted *FT* against the measured flowering times.

Mathematically speaking, if fl(ph) is an experimental measure of flowering fl (for example, leaf number) in a photoperiod ph, and Q refers to a molecular quantity (FT mRNA concentration, for example), then flowering fl under photoperiod ph is a function of Q under photoperiod ph. This relationship is defined by function X (in our example, X is relationship of leaf number to FT mRNA concentration), thus:

$$fl(ph) = X(Q(ph)). (7)$$

As fl(ph) is known experimentally and our molecular models will give us an approximation to Q(ph), which we will call $Q^*(ph)$, then we can compute an approximation to X (termed X^*) using measured fl(ph) values from the literature:

$$fl(ph) = X^*(Q^*(ph)). \tag{8}$$

Using X^* we can obtain by interpolation an approximation to fl(ph), $fl^*(ph)$, for other photoperiods that have not been measured:

$$f(f(ph)) = X^*(Q^*(ph)).$$
 (9)

We analysed flowering-time data of Corbesier *et al.* (Corbesier et al., 1996), which offers several useful data sets, by this method to illustrate the approach. The data include flowering time (as "days to macroscopic appearance of flower buds") of non-vernalized Columbia plants under various photoperiods (in figure 1 of the paper), and flowering time (as

"percentage of [plants showing] flower induction") of vernalized Columbia plants maintained in SD for 2 months then treated with a single test cycle of various photoperiods (in figure 3a). In order to compute $Q^*(ph)$ for the conditions used in Figure 1, model 3b was entrained to light:dark cycles with various photoperiods and FT mRNA area was calculated (the area beneath the curve of FT mRNA level integrated over a 24h cycle). Thus the full model provides $Q^*(ph)$ in a complex form. The same relationship between FT area and photoperiod can be more simply approximated by a quadratic function (see Supplemental figure 5), given by

$$FTarea = 0.12ph^2 - 2.1ph + 12. (10)$$

The data point for a 24h photoperiod (constant light) also fits the quadratic relationship well.

 $X^*(Q^*(ph))$ could be computed in several ways, depending on the data. The measured flowering times in Figure 1 of (Corbesier et al., 1996) exhibit a switching behavior when plotted against either photoperiod or FT area, which can be approximated by a sigmoid function. The change in flowering time is greatest between 8h photoperiod (>80 days to flowering) and 12h photoperiod (~30 days), where predicted FT area is low and changes relatively little (supplemental figure 6a). The leftmost point is therefore in a region of very steep gradient, where flowering times change quickly for even a slight change in FT area. It is unclear where the flowering times will saturate, and in practice growth rates may be markedly reduced under very short photoperiods owing to metabolic effects. No saturating sigmoid function was found to match these data as well as a non-saturating function, given by

Flowering time =
$$d0 + a / (1 - FTarea/b)$$
 (11)

where *d0* is a minimum flowering time at very high *FTarea* (estimated at 16.55 days), *a* is a multiplier (estimated at -15.29), *FTarea* is as described above and *b* is an artificial lower limit of *FT* area that prevents flowering completely (estimated value 1.63). Supplemental figure 6a shows this function plotted together with the most closely-matching Hill function,

$$Data = d1 + a1 \frac{b1^{n}}{b1^{n} + FTarea^{n}}$$
 (12)

with parameter values a1 = 662.081, b1 = 0.93871, n = 1 and d1 = 16.5 days. In this function, d1 is again the minimum flowering time, a1 is a multiplier, b1 is the *FTarea* at the so-called "critical photoperiod", and n is the Hill coefficient. The critical photoperiod is conventionally defined as the photoperiod that causes the half-maximal flowering response, between the fully-induced and fully-uninduced conditions. Higher Hill coefficients allow a sharper switch from the uninduced to the induced response, over a narrower range of *FTarea*. Because this data set did not include sufficiently short photoperiods to indicate the maximum flowering time, the limits of the response were unclear: the Hill coefficient was set to 1 and the value of b1 was also poorly constrained.

Data sets that include a greater range of photoperiods can show that the flowering response is minimally induced at short photoperiods and is saturated at long photoperiods. The Hill function (12) is equally applicable to data for flowering time (days to flowering) and for leaf numbers, as high leaf numbers at flowering reflect late flowering time. Equation (12) can therefore match the leaf number data of Pouteau *et al.* for the Ws accession (Pouteau *et al.*, 2008) and the leaf number data of Wilczek *et al.* for the La(*er*) accession (Wilczek *et al.*, 2009). For Wilczek *et al.* (Figure 5B), best-fit parameter values are n = 10, d1 = 10, a1 = 30.0669 and b1 = 2.82065. For Pouteau *et al.* (Figure 5C), best-fit parameter values are n = 6, d1 = 15, a1 = 31.9573 and b1 = 2.88922. In these cases, d1 is the minimum leaf number observed with fully-induced flowering, which is lower in the La(*er*) data than in Ws. Note the high values of n, which confer switching behaviour, and the very similar estimates of *b1*, which reflect similar critical photoperiods in both data sets.

Equation (12) can be directly related to the photoperiod submodel in the recent phenological model for Arabidopsis (Wilczek et al., 2009). Parameter d1 corresponds to the reciprocal of the developmental rate for photoperiods below the critical short day length. The upper and

lower turning points on either side of the critical day length correspond to the FTarea at the critical long and short day length (Wilczek et al., 2009), respectively.

In order to compute $Q^*(ph)$ for the conditions used in Figure 3 of (Corbesier et al., 1996), model 3b was entrained to SD (8L:16D) cycles and then tested under one longer photoperiod. Within the single, test photoperiod the model exhibited little change in mCO waveform compared to the preceding SD conditions (data not shown), because the entrainment of the clock was hardly affected within the first photoperiod. The mFT waveform was changed by the longer light intervals, resulting in a steep linear increase in the FT area (Supplemental figure 5). Note that this contrasts with the quadratic increase observed for the simulations under continuous cycles of altered photoperiod, where the entrainment of the clock also varies with the photoperiod (Supplemental figure 5; see Discussion).

 $X^*(Q^*(ph))$ was fitted with a sigmoid function, assuming that flowering was maximally induced by a 20L:4D cycle :

% Flowering Indunction =
$$k1 \frac{(FTarea - FTarea(SD))^n}{P_crit^n + (FTarea - FTarea(SD))^n} + k0$$
 (13)

where k0 = 0, the % flowering in the SD control plants, k1 = 100 for full induction, $P_crit = 3.97$ and the best value for n is probably 9. This represents a very steep switching behavior, very similar to what is observed in Figure 3(a) of (Corbesier et al., 1996) (Supplemental figure 6b).

Overall, this analysis supports the use of the *FT* area as a relevant model output for flowering prediction. Functions similar to (11), (12) and (13) above can readily be adapted to accommodate the variations in flowering time due to the growth conditions of specific laboratories, so that the model-based estimate, *X*(FTarea*(ph))*, can be used to interpret molecular data. Multiple data sets with matched FT areas and flowering times are now

required to define a measured X(FTarea(ph)) function, in order to validate the model-based estimate and to assess the variations among laboratories.

Photoperiod responses over multiple cycles and transient changes in photoperiod In order for the plant to integrate the FT over a full diurnal cycle, as FTarea does in the model, a moderately stable molecule may be required downstream of the FT mRNA. Levels of this integrating molecule would then cross a threshold for flowering upon a single long photoperiod, in the case of the SD-grown plants in Figure 3a of (Corbesier et al., 1996). The effective stability of the integrator must be limited, however, to ensure that the current or most recent photoperiods have the greatest effect. Excessive stability would allow long-term accumulation to induce flowering in plants held under SD conditions for 2 months without an inductive photoperiod, in contradiction to the data (Corbesier et al., 1996). Where young seedlings are tested (for example, Corbesier et al., 2007), several LD are required to induce flowering, indicating that the integrating species is stable enough to accumulate over several days. FT expression also increases progressively after each LD, and one cycle with high FT expression is observed after plants are returned from LD to SD (Corbesier et al., 2007). The latter effects are suggestive of a positive feedback in the photoperiod sensor. As the mechanism(s) of these effects remain to be determined, they are not included in the models presented.

Daylength perception in a short-day plant

A dramatic re-tuning of the photoperiod sensor is thought to have occurred in rice, to promote flowering in SD rather than LD (Hayama and Coupland, 2004). The CO orthologue of rice, Heading date 1 (Hd1), is expressed in a very similar fashion to Arabidopsis CO under both LD and SD (Supplemental figure 8a). Rather than activating expression of FT as in Arabidopsis, genetic evidence indicates that Hd1 suppresses the best-characterised rice homologue of FT, named Hd3a (Hayama and Coupland). This change of sign has been proposed to account for the difference in mechanism between short-day plants and long-day

plants (Hayama et al., 2003). The published timeseries data for these rice genes are fewer and more variable than in Arabidopsis. Nonetheless, modeling of the rice data set that is most similar to Arabidopsis showed that, even for these data, the change of sign does not account for the dynamic expression pattern of *Hd3a* (data not shown). The same conclusion can be reached by inspection of the data (Supplemental figure 8b): light coincides with the highest *Hd1* RNA levels 12h after dawn under LD, but this peak of *Hd1* passes in darkness under SD. If light interacts with *Hd1* as it does with *CO*, this should result in differential induction of *Hd3a* in LD versus SD, yet *Hd3a* RNA levels at this time are almost identical in both conditions. Furthermore, about 4h after dawn *Hd1* expression falls to similar, low levels under LD and SD, yet this is when *Hd3a* RNA levels show the greatest photoperiodic regulation.

We propose that the coincidence of *Hd1* with light sets the mean level of *Hd3a* expression but that the phase of expression is set by another rhythmic factor, which we term the Circadian Regulator of *Hd3a* (CR3a). Activation of *Hd3a* transcription may for example require interaction between the Hd1 protein and a rhythmically expressed transcription factor. CR3a can be equally well approximated using a sine wave (Supplemental figure 8) or the waveform of *Hd1* RNA (unpublished results). CR3a can be modeled as either an activator or repressor of Hd3a, where activating CR3a peaks shortly after dawn (as in Supplemental figure 8) or repressive CR3a peaks early in the night (unpublished results).

$$\frac{dmHd3a}{dt} = B + vHd1 \cdot \frac{kHd1}{1 + \left(kHd1 + INT\right)} - vHd3a \cdot \frac{mHd3a}{kHd3a + mHd3a} + vCR3a \cdot \frac{CR3a}{kCR3a + CR3a}$$
 (13)

$$CR3a = 1 + \cos\left(\frac{2\pi(t + \phi_{CR3a})}{\tau_{CR3a}}\right) \tag{14}$$

B = basal level of *Hd3a* transcription (0.05 nmol/h), *vHd1* = maximum *Hd3a* transcription antagonized by Hd1 inhibition (2.545 nmol/h), *kHd1* = Michaelis constant of inhibition by Hd1 (2.3291 nmol), *INT* = measured integral of *Hd1* mRNA area during light interval over one 24h

cycle (1.39 nmol under 10L14D, 4.32 nmol under 14L10D), vHd3a = maximum rate of Hd3a mRNA degradation (1.9861 nmol/h), kHd3a = Michaelis constant of Hd3a degradation (0.0327 nmol), vCR3a = maximum Hd3a transcription rate from CR3a activation (4.4770 nmol/h), kCR3a = Michaelis constant of activation by CR3a (10.9056 nmol), Φ_{CR3a} = phase of CR3a transcription (-0.6242 h), τ_{CR3a} = period of CR3a transcription (24h).

Moreover, the relevant coincidence of *Hd1* with light cannot result in immediate regulation of *Hd3a*, nor can the coincidence be integrated uniformly within the day starting from dawn, as both mechanisms would predict the greatest difference in *Hd3a* expression at the end of the day. We therefore propose that the coincidence of *Hd1* RNA with light is integrated over longer time intervals spanning several days, and that this integrated measurement sets the mean level of *Hd3a* expression. The rice mechanism is therefore quite distinct from the very rapid effect in Arabidopsis of the coincidence of CO with light. Supplemental figure 8 shows that this class of mechanism readily fits the data. A parsimonious molecular mechanism is that Hd1 protein is much more stable than CO, accumulating over several days. A paralogue of CO that is rhythmically expressed with a peak near dawn (Kim et al., 2008), like CONSTANS-LIKE1 in Arabidopsis (Ledger et al., 2001), might function as an activating CR3a, though Hd1 is also proposed to have activating functions (see references in main text).

Supplemental figure legends

Supplemental figure 1. Molecular data from several laboratories conform to the external coincidence hypothesis.

The validation data (see Supplemental Data; Supplemental Table 1) were analysed to identify the trends across all experiments. (a) The integrated FT mRNA area over one cycle is strongly correlated with the integrated CO mRNA area during the light interval. (b) the integrated FT mRNA area over one cycle is more flexibly related to the hours of light during the cycle. The experimental mRNA levels have been normalized to the CO mRNA maximum (see Supplemental data). (c) Simulations of models 1a (blue symbols) and 1b (green symbols) optimized using the training data were then compared to the validation data of (b). (d) Simulations of model 3 (black symbols) were compared to the validation data of (b). In each case, solid lines show a linear fit to the cognate data series, indicating the overall trend of the data or simulations.

Supplemental figure 2. The *toc1* mutation has little effect on light activation of *FT*. Data redrawn from (Yanovsky and Kay, 2002) depict mRNA levels of *CO* (open symbols) and *FT* (filled symbols) in the *toc1-1* mutant under light:dark cycles of 21h (**a**, **b**, **e**, **f**, T=21h) or 24h (**c**, **d**, **g**, **h**, T=24h). In each case, short (**a**, **c**, **e**, **g**) and long (**b**, **d**, **f**, **h**) photoperiod conditions are shown. The simulated *FT* mRNA levels (solid line) are shown, from simulations using model 1a with parameters optimised for the wild type (a-d) or model 1a with parameter *Vco* altered to match the *toc1* data sets, changing from 26 nmol/h in wild type to 37 (e, f) or to 35 (g, h).

Supplemental figure 3. *CO* activates less *FT* expression in the early morning. The over-activation of *FT* mRNA in model 1a (Figure 2) was estimated by reducing the effectiveness of light in activating *FT* in the morning. Best-fit parameters for the duration and extent of this morning gate were estimated by fitting simulations (solid lines) based on observed *CO* mRNA levels (blue circles) to observed *FT* mRNA levels (red diamonds) from the two training data sets (Imaizumi et al., 2003; Yanovsky and Kay, 2002), under SD (**a, b**) and LD (**c, d**). The effects shown for SD are duration 2.3 h, effective light intensity 60% of normal; and for LD, duration 5 h, intensity 40% of normal.

Supplemental figure 4. Simulating the effect of FKF1 on *CO* expression.

(a) Accumulation patterns of FKF1 protein under 8L:16D ('SD') and 16L:8D ('LD'), redrawn from Imaizumi *et al* (2003). (b) The additional *CO* transcription due to FKF1 activation under 16L:8D is plotted alone (dashed line) and superimposed (dotted line) upon the original rate of *CO* transcription from model 3 (solid line). The mRNA expression patterns for *CO* (c) and *FT* (d) were simulated by model 3F1 including the activation of *CO* by FKF1 protein (solid lines), with the corresponding experimental data (diamonds). (e) depicts the circuit originally proposed by Imaizumi *et al.* (2003).

Supplemental figure 5. Entrainment of the circadian clock contributes to the photoperiod switch.

Model 3 was stably entrained to 24h cycles with various photoperiods, as in Figure 1 of Corbesier *et al.* (1996). The *FT* mRNA area integrated over 24h of simulation is shown (open diamonds, with quadratic fit). Alternatively, *FT* mRNA area was measured following transfer from 8L:16D short photoperiods to a single test photoperiod of the duration shown (filled circles, with linear fit), as in Figure 3 of Corbesier *et al.*, (1996).

Supplemental figure 6. Effective relationships between the predicted *FT* area and flowering time in the Columbia accession.

The FT areas predicted in Supplemental figure 5 are plotted against the flowering time data of Corbesier et al. (1996), Figure 1 (a) and Figure 3 (b). The relationships are described by two effective functions (a, see legend), or by a sigmoid function (b). Parameter values are given in the Supplemental data, equations (11) - (13). Figures beside each data point show the cognate photoperiod (h).

Supplemental figure 7. Functional CO protein is not required to produce the *FKF1*-dependent shoulder of *CO* mRNA in long photoperiods.

(a) Hypothetical circuit, in which the dual effects of *FKF1* on *CO* and *FT* mRNA are accomplished by a single molecular function of FKF1 at the level of CO protein. CO protein is proposed to feed back to regulate the shoulder of *CO* mRNA. Under this model, mutation of *CO* should prevent the FKF1-dependent activation of *CO* transcription in long photoperiods.

(b) Seedlings with and without *co* mutations were grown under 16L:8D for 10 days at 22°C. Samples were harvested 13h after lights-on, and extracted RNA was analysed by qRT-PCR. The *fkf1* mutant strongly reduces *CO* mRNA expression at this time, but *co* mutations have little or no effect. Filled bars, wild types and *fkf1* mutant control. Col, Columbia parent; Ler, Landsberg *erecta* parent. Open bars, *co* mutant alleles. The *co-SAIL* allele is line SAIL_24_H04 and lacks *CO* mRNA due to a T-DNA insertion (nd, not detectable).

Supplemental figure 8. The molecular photoperiod response in rice. mRNA expression profiles are shown for the CO homologue Hd1 (a) and the FT homologue Hd3a (b), under 10L:14D (open symbols, SD) and 14L:10D (filled symbols, LD), from (Hayama et al., 2003). Simulated Hd3a expression is shown under SD (bold solid line) and under LD (solid line). (c) shows the hypothetical circuit, in which the coincidence of light with Hd1 expression is integrated (\int) before it inhibits expression of Hd3a. A hypothetical circadian regulator (CR3a) controls the timing of Hd3a expression during the diurnal cycle. Hd3a promotes flowering, as FT does in Arabidopsis.

Supplemental Table 1. Data provenance and file names.

Publications that provided the mRNA waveforms are listed below. The numerical values of the cognate data sets are available as supplemental data in the draft CSBE standard format. Each waveform is assigned a name, including the genotype and experiment number. Corresponding *CO* and *FT* waveforms share the same experiment number. Levels were measured by RT-PCR, with detection either by real-time fluorescence labelling or by hybridisation of radio-labelled probes. The mRNA used as a constitutive control for inter-sample normalization varies. Primers that amplify *UBIQUITIN* (*UBQ*) transcripts (Blazquez and Weigel, 1999) were used in experiments 1-12 and similar primers (Cerdan and Chory, 2003) for experiments 13 and 14. Experiment 15 (Somers et al., 2004) used *ACTIN2* (*ACT2*). In one experiment, the ratio *FT/CO* was quantified directly (Valverde et al., 2004). Notes: LD – long days; SD – short days; a plus sign indicates wild-type genotype.

Supplemental Table 2: predictions from the models.

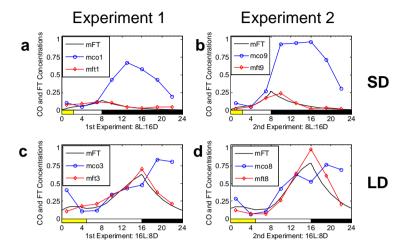

Specific predictions, gaps in data and future experiments highlighted by the models are listed. Many additional predictions (the values of the parameters, for example) and gaps in data (quantitative time series of protein accumulation in the wild type, for example) are generic and are not listed here.

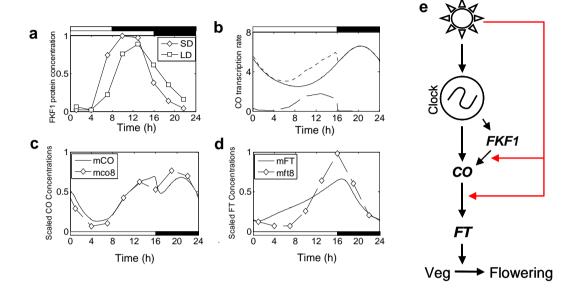

| | Prediction or Gap | Model | Outcome | Possible experiments |
|---|-----------------------|--------|--|---|
| 1 | Prediction and Gap | 1 | Effectiveness of <i>CO</i> mRNA in activating <i>FT</i> is reduced by ~60% in the first 5h of light in long photoperiods, but less in short photoperiods. This avoids a morning peak of <i>FT</i> expression. The effect of <i>FKF1</i> (see 6, below) is a possible mechanism. | Identify unknown factor that modifies <i>FT</i> activation in this pattern, e.g. quantify CO protein levels in WT compared to mRNA. |
| 2 | Prediction | 1 | <i>TOC1</i> has little (40% or less) effect on the light activation of <i>FT</i> transcription; <i>toc1</i> 's main effect on photoperiodism is <i>via</i> the rhythm of <i>CO</i> transcription. | Quantify FT mRNA levels in response to light in toc1 and wild type. |
| 3 | Prediction | 2 | The phase of circadian regulation of the <i>CO</i> mRNA changes significantly under different photoperiods, similar to <i>TOC1</i> in the interlocking-loop model. | Test <i>CO</i> mRNA phase under a range of photoperiods, compared to other clock genes. |
| 4 | Gap | 2 | Insufficient data on the phases of clock components under different photoperiods. | As for point 3, above. |
| 5 | Prediction | 2 | The waveform of <i>CO mRNA</i> is modified by <i>FKF1</i> , which mediates up to a 45% increase in <i>CO</i> transcription rate over the last 8h of a long photoperiod, with much less effect in SD. The effect on <i>CO mRNA</i> turns on and off sharply. This creates the photoperiod- and <i>FKF1</i> -dependent shoulder in <i>CO</i> expression. | As for point 3, above, with additional tests in <i>fkf1</i> . |
| 6 | Prediction and Gap | 3, 3F2 | FKF1 very strongly promotes FT transcription (~10-fold increase in transcription rate at the end of a long photoperiod). | Test <i>FKF1</i> association with <i>FT</i> promoter. |
| 7 | Prediction | 2,3 | The <i>FKF1</i> effect on <i>FT</i> is similar to the effect on <i>CO</i> (see 5), for example in its photoperiod-dependence. Both effects of <i>FKF1</i> might have similar mechanisms. One hypothesis was that both were mediated by CO protein. | Testing <i>CO</i> mRNA under LD in <i>co</i> mutants showed no effect on the <i>FKF1</i> -dependent shoulder (sup. figure 8). |
| 8 | Prediction | 3 | Discrimination between long and short photoperiods will be optimal for cycle | Measure flowering time under a range of different |

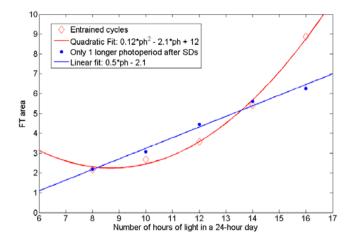

| | | | durations close to 24h; short photoperiods are partially inductive in longer or shorter cycles. | photoperiods, each in a range of cycle durations. |
|----|------------|---|---|---|
| 9 | Gap | 4 | Insufficient data to quantify the non-linear response of flowering time to <i>FT</i> . | Measure <i>FT</i> expression profiles and flowering time under a range of photoperiods. |
| 10 | Prediction | 4 | The response measured in 9 will be approximated by equations (10, 11), up to the latest flowering times shown (sup. Figure 6). Later flowering times cannot yet be predicted. | As for point 9, above. |
